Abstract: Powder metallurgy Ti−45Al−10Nb alloys was successfully fabricated by reactive sintering of milled powders at 1350 °C for 2 h in vacuum. The microstructure, in particular, constituent phases, grain size, precipitates of the product was investigated in detail. The results indicate that a double phase $\gamma+\alpha_2$ microstructure containing Ti$_2$AlC precipitate is obtained under the sintering condition, and the alloy exhibits a fine and homogenous microstructure compared with traditional TiAl base. In fine grain structure, the average grain sizes for the $\gamma$ and $\alpha_2$ phases are (2.3±0.05) and (5.6±0.05) $\mu$m, respectively. Additionally, numerous dislocations are observed in the alloy, and the dislocation density in $\gamma$ phase is significantly higher than that in $\alpha_2$ phase. The formation mechanisms of the dislocation in the present alloy were also discussed in detail.

Key words: high Nb–TiAl alloy; powder metallurgy; microstructure; dislocation

1 Introduction

TiAl based alloys are highly promising for elevated temperature structural applications in aerospace and automotive industries, due to their attractive properties, such as low density, good elevated temperature strength, high resistance to oxidation, and excellent creep properties [1–3]. However, the low room temperature ductility and poor deformability cause the conventional manufacturing operations such as rolling, forging, or drawing to be difficult and has restricted their application [4,5]. Accordingly, it is of great significance to develop effective techniques for preparation and forming for this alloy system. The powder metallurgy (PM) process is a near-net or net-shape manufacturing process and has been considered to be an attractive process in order to produce TiAl alloys with a fine-grained microstructure [6,7]. Compared with IM processes, PM methods, when a pre-alloyed TiAl powder is used, can decrease the retention of $B2$ phase in the microstructure [8], and fine and homogenous microstructure can be obtained. Besides, the PM-TiAl alloy does not need the subsequent strenuous thermomechanical process aiming to obtain a fine and homogenous microstructure, which is indispensable to the TiAl alloy fabricated by IM due to the solidification defects [9]. Among the powder metallurgy techniques studied recently, elemental powder metallurgy (EPM) has drawn intensive attention because of its low cost, good formability and convenient addition of alloy elements. Thus, some efforts have been conducted to the fabrication of the TiAl alloy through the EPM process [10–12]. However, the reactions taking place in such process are often complicated and have not been well understood due to the TiAl matrix phases formed as a result of complex reactions during the consolidation. Thus, we investigated the phase formation and the microstructure in the Ti−Al−Nb systems after the fabrication of the TiAl alloy. It is expected that the understanding of the reaction behaviors in the present systems can permit a better control of the reaction process through the regulation of processing parameters, and also provide a guide for producing the high-content Nb TiAl alloys with tailored microstructures and properties.

In the present work, PM Ti−45Al−10Nb (mole fraction, %) alloys were synthesized with the mechanical milling and reactive sintering process. The results of investigations on the microstructural development within the sintered alloy, as well as the formation mechanisms, were reported here. It is expected that this study would further promote the development and engineering applications of high niobium containing gamma TiAl alloys.
2 Experimental

Commercial powders of Ti (99.6% purity, ~44 μm), Al (99.9% purity, ~47 μm), Nb (99.6% purity, ~44 μm), and stearic acid (C_{18}H_{36}O_{2}) were used as the starting materials. Ti–45Al–10Nb alloy with stearic acid addition of 1% (mass fraction) was fabricated by an elemental powder metallurgy process which involves mechanical milling and subsequent reactive sintering. The synthesis of the milled powders to fully dense compacts was conducted at 1350 °C under load of 50 MPa for 2 h with a heating rate of 5 °C/min, and then the compacts were annealed at 1050 °C for 2 h. The phase contents of as-fabricated alloys were examined by X-ray diffraction (XRD) using Cu Kα radiation (λ=0.1546 nm). The detailed microstructures were subsequently examined using optical microscopy (OM), scanning electron microscopy (SEM) and transmission electron microscopy (TEM). SEM observations were operated on an FEI Quanta 200F scanning electron microscope, equipped with backscattered electron image. Conventional TEM observations were operated on a FEI Tecnai F30 operating at 130 kV. TEM foils were prepared by a standard twinjet electropolishing technique in an electrolyte of 60% methanol, 35% butyl alcohol and 5% perchloric acid at ~15 V and ~30 °C.

3 Results and discussion

3.1 Phases of as-prepared TiAl alloys

An XRD pattern generated from as-prepared TiAl alloy of composition Ti–45Al–10Nb is shown in Fig. 1. It reveals that the alloy primarily consists of γ phase, α_{2} phase and a small amount of Ti_{2}AlC phases. The volume fraction of Ti_{2}AlC phase calculated by the adiabatic method according to the XRD result is about 8.9%. The carbon element in the Ti_{2}AlC phase was from the decomposition of the stearic acid C_{18}H_{36}O_{2}. When the sintering temperature was about 400 °C, the stearic acid was decomposed, and the carbon was left in the composite powder. Moreover, the diffusion peak of Nb was not detected in the TiAl composites. According to previous work [13], Nb has a solubility of about 20% in TiAl alloys, depending on temperature. The Nb element in the TiAl composites is mainly in the form of solid solution. This result indicates that two-phase TiAl composites reinforced with Ti_{2}AlC could be fabricated in situ by the method of the hot press consolidation of milled powder in the Ti–Al–Nb–C system. Based on these considerations, a detailed analysis of the sintered microstructures is presented in the following sections.

3.2 As-sintered microstructure

In general, a two-phase (γ and α_{2}) fully lamellar microstructure is developed in the α-phase field within the alloys fabricated at 1350 °C. Figure 2 shows the microstructures of the sample sintered at 1350 °C. Obviously, a distinct microstructure marked by A and B can be observed in different regions of the micrograph shown in Fig. 2(a). Detailed views of regions A and B in Fig. 2(a) at high magnification are shown in Figs. 2(b) and (c), respectively. In region A, grayish precipitates are homogeneously dispersed in the matrix. EDX point analyses have shown that in the grayish particle, the mole fractions of Ti, Al and Nb elements are 59.14%, 34.58% and 6.18%, respectively. According to the above XRD results, the grayish phase is identified as Ti_{2}AlC. On the reverse, in region B (Fig. 2(c)), the Ti_{2}AlC precipitate is less discernable. EDS analyses have shown that Nb is concentrated in these regions, as shown in Table 1. This explains why the phases in region A exhibit a clearer bright contrast than those in region B. The OM images of the two areas are shown in Figs. 3(a) and (b), respectively. It is clear that, in region A, the alloy shows duplex microstructure made of a mixture of lamellar colonies and of γ grains. A great deal of twin structures can also be observed. However, in region B, the microstructure is near full lamellar (α_{2} and γ plates) with a grain size of 20–60 μm (Fig. 3(b)). In addition, there is a very small percentage of equiaxed γ phase, which exists at the grain boundaries. The presence of lamellar colonies in the sintered condition can be ascribed to the fact that the sintered temperature is above T_{γ}. Evidently, inhomogeneity of the microstructure of the sintered alloy is caused by the distribution of elements in the milled powder.

To further investigate the structure and composition of the micro-constituent phases within the microstructures mentioned above, TEM analysis was performed. A typical microstructure can be found in

![Fig. 1 XRD pattern (Cu Kα) generated from as-prepared alloy sample](image)
different regions of the micrograph shown in Fig. 4(a). According to selected area diffraction (SAD) analyses, the coarse grains (1–4 μm) in the middle region have α₂ structure and the fine grains (0.5–1 μm) around the coarse grains are mainly a mixture of γ and α₂ grains. The two-phase microstructure composed of equiaxed γ (L1₀, TiAl) and α₂ (DO₁₉, Ti₃Al) grains were formed via the α→γ+α→γ+α₂ transition reactions. Typical lamellar microstructures within colony grains observed from the sintered alloys are shown in Fig. 4(b). The colony grain sizes are 20–60 μm, the width of γ lamellae varies between 0.17 μm and 1.2 μm and the width of α₂ lamellae varies between 0.06 and 0.41 μm. These values are considerably finer than the values in lamellar TiAl alloys fabricated by conventional processing techniques [14,15]. In addition, the alloy also contains many elongated grains of Ti₂AlC phase, as shown in Fig. 4(c). The [T₀₁₀]₉₀₁₅ zone diffraction pattern of the Ti₂AlC phase is shown in Fig. 4(d). The synthesized Ti₂AlC particles mainly distribute at grain boundaries, which can improve the strength of TiAl composite. Despite some heterogeneities in the local chemical composition and the repartition of the Ti₂AlC precipitates detected, the alloy exhibits much fine-grained microstructure compared with traditional TiAl base. To homogenize the alloy at the aim of improving its properties, subsequent thermal treatments would be performed.

3.3 Dislocations in as-sintered alloy

As illustrated in Fig. 4(c), in the γ phase, numerous dislocations are generally curved or bowed and dislocation lines are extensively intersected and pinned.
The dislocations in the lamellae and at the grain boundary gamma in lamellar samples are mostly \( 1/2(110) \) ordinary dislocations but some are \( 1/2(112) \) super-dislocations. They are believed to originate from the thermal stresses (coherency stress) generated between different lamellae during cooling from high temperature. Other types of dislocations are also identified in the sintered microstructure, as indicated in Fig. 5. Figures 5(a) and (b) show rectilinear dislocations which are anchored at many pinning points, as very frequently observed in the \( \gamma \) phase of deformed TiAl alloys [16,17]. Such morphology illustrates that slip systems are operating simultaneously and locks are formed during the densification step. The dislocation density in \( \gamma \) phase is obviously higher than that in the \( \alpha_2 \). The high density of dislocations confirms that the \( \gamma \) grain

**Fig. 3** OM micrographs of Ti–45Al–10Nb sample sintered at 1350 °C with double-phase microstructure: (a) Duplex microstructure in region \( A \) of Fig. 2; (b) Near full lamellar (\( \alpha_2 \) and \( \gamma \) plates) in region \( B \) of Fig. 2

**Fig. 4** TEM micrographs of duplex microstructures: (a) Coexistence of coarse \( \alpha_2 \) grains with fine-grained \( \gamma \) structure; (b) \( \alpha_2/\gamma \) lamellar grain; (c) Elongated Ti\(_2\)AlC grains; (d) \( [\overline{1}010]_{\text{T}_1\text{AlC}} \) zone diffraction pattern of Ti\(_2\)AlC phase
is not recrystallized, but strongly deformed at the end of the reactive sintering process. Similar anomalous microstructure has been observed in γ-TiAl alloys [18].

4 Conclusions

1) The microstructure of powder metallurgy TiAl alloys with nominal compositions Ti–45Al–10Nb consists of double-phase (α2+γ) microstructure containing some fine Ti2AlC ceramic precipitates.

2) The coarse grains of α2–γ lamellar and fine grains of γ and α2 are found in the sintered compacts. The heterogeneities in the local chemical composition and the repartition of the B2 precipitates are also detected.

3) The dislocations in the lamellae and at the grain boundary gamma in lamellar samples are mostly 1/2⟨110⟩ ordinary dislocations. The dislocation densities in γ phase are higher than those in α2 phase.
