Received 27 April 2013; accepted 30 October 2013

**Abstract:** The hierarchically porous carbons (HPCs) were prepared by sol-gel selassembly technology in different surfactant concentrations and were used as the potential electrode for lithium oxygen batteries. The physical and electrochemical properties of the as-prepared HPCs were investigated by filed emission scanning electron microscopy (FE-SEM), transmission electron microscopy (TEM), nitrogen adsorption-desorption isotherm and galvanostatic charge/discharge. The results indicate that all of the HPCs mainly possess mesoporous structure with nearly similar pore size distribution. Using the HPCs as the electrode, a high discharge capacity for lithium oxygen battery can be achieved, and the discharge capacity increases with the specific surface area. Especially, the HPCs-3 oxygen electrode with CTAB concentration of 0.27 mol/L exhibits good capacity retention through controlling discharge depth to 800 mA·h/g and the highest discharge capacity of 2050 mA·h/g at a rate of 0.1 mA/cm<sup>2</sup>. **Key words:** lithium oxygen battery; hierarchically porous carbon; oxygen electrode; oxygen reduction

## **1** Introduction

Metal oxygen batteries have much higher specific energy than most available primary and rechargeable batteries in which their active cathode materials, and oxygen can be accessed from the environment. Lithium air (oxygen) batteries have the highest theoretical specific energy among all metal oxygen batteries because of the high specific energy of lithium metal. The theoretical specific energy of lithium air (oxygen) batteries is 11140 W·h/kg, excluding O<sub>2</sub> (5200 W·h/kg including O<sub>2</sub>). The present lithium air (oxygen) cell appears to be rechargeable due to the use of nonaqueous electrolyte [1-3]. The first lithium oxygen battery with nonaqueous polymer electrolyte was reported in 1996 by ABRAHAM and JIANG [4]. Prototype lithium oxygen batteries typically consist of a lithium-metal anode, organic electrolyte and a porous carbon-based cathode exposed to gaseous O<sub>2</sub> during cell operation [5]. In an organic system, the discharge mechanism was determined to be primarily the deposition of Li<sub>2</sub>O<sub>2</sub> in the porous structure of the oxygen electrode, and discharge ceases when the porous cathode is completely filled with these reaction precipitates.

There is an urgent need to design and synthesize a highly effective carbon cathode for high-performance lithium oxygen batteries. Recently, intensive research effort has been devoted to improve the performance of lithium oxygen batteries by tuning the morphology and structure of the carbon cathode. KUBOKI et al [6] compared the effect of the specific surface area and pore volume of porous carbon on discharge performance of lithium oxygen battery. It has been found that the pore volume has a more marked effect on specific capacity than the surface area. Another study carried out by YANG et al [7] showed that the porous carbon material with a significantly lower surface area but a much larger pore size displayed much better electrochemical performance than one with higher surface area but smaller pore size. And different kinds of carbon, including high-surface area carbons [8-12], mesocellular carbons, carbon nanotube [13-16], carbon fiber or carbon paper [17], and graphene [18–20], have been

used as O<sub>2</sub> electrodes in lithium oxygen battery. However, different kinds of porous carbon materials represent apparently different characteristics when they are used as oxygen electrode. Among all porous carbon materials, the mesoporous carbon materials lead the electrolyte ions to transport into the bulk of material quickly and also provide larger space for formation of discharge products, thus the mesoporous carbon materials are often used to improve discharge performance of the lithium oxygen batteries [21]. In contrast, the porous carbon materials with micropore size are not be suitable in lithium oxygen batteries because small pores could be easily choked by discharge product [22].

Hierarchical porous carbons (HPCs) with a multimodal pore size distribution of micro-, mesoand/or macro-pores show high electrochemically accessible surface area, short diffusion distance, and high mass transfer rate when used as electrode materials in energy storage devices [23-25]. If the size of pore is further controlled, it will reveal some excellent electrochemical performance, so it will be an interesting work for using the hierarchical porous carbons with mesoporous structure as the oxygen electrode of lithium oxygen battery. Recently, our group has carried out a lot of researches on hierarchical porous carbon materials and their supercapacitive behaviors [26–30]. In this work, the hierarchically porous carbons (HPCs) with meso-porous structure are prepared by sol-gel self-assembly process with nickel oxides and surfactant as the templates and are used as oxygen electrode of lithium oxygen batteries. The discharge behavior and battery characteristics of lithium oxygen battery are investigated in detail.

### **2** Experimental

Hierarchically porous carbons [26] were prepared by carbonization and corrosion of the dual template precursor. A solution of phenolic resin (PF) in ethanol as the source of carbon was added into the mixture of cetyltrimethyl ammonium bromide (CTAB), nickel nitrate hexahydrate (Ni(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O) and sodium hydroxide (NaOH) with sufficiently stirring. The mixture was left with a blending-layered-settlement program and dried in air at 60 °C for 12 h. The sample was heated to 200 °C (5 °C/min) and maintained for 2 h in pure argon, then heated to 600 °C (5 °C/min) and maintained for 5 h, and finally cooled down naturally to room temperature. The resultant product was etched with 3 mol/L HCl thoroughly to remove Ni(OH)2/NiO, then filtered and washed several times with deionized water and dried in an oven at 100 °C, finally treated with 2 mol/L HNO<sub>3</sub>. During preparation process, the molar ratios of  $Ni(NO_3)_2$ and CTAB were 4:0, 4:2, 4:4, and 4:6, and the corresponding CTAB template concentrations were 0, 0.14, 0.27, and 0.41 mol/L, respectively. The as-prepared samples were denoted as HPCs-1, HPCs-2, HPCs-3, and HPCs-4, respectively.

The porous properties of HPCs were characterized by adsorption experiments of nitrogen, and adsorption/ desorption isotherms of nitrogen were measured at 77 K on a Quantachrome autosorb automated gas sorption system. The estimation of the Brunauer–Emmett–Teller (BET) specific surface area (SSA), pore volume and pore size distribution (PSD) were carried out according to the Barrett–Joyner–Halenda (BJH). Filed emission scanning electron microscope (FE-SEM) (Sirion 200, FEI) and transmission electron microscope (TEM) (JEM–2100F, JEOL) were used to study the morphology and size of HPCs.

The oxygen electrode was fabricated by compressing a mixture of carbon material (HPCs) and poly (vinylidene fluoride) binder with a mass ratio of 9:1 onto a nickel foam current collector. The geometric surface area of the oxygen electrode disks was kept to be  $0.785 \text{ cm}^2$  and the typical loading of the oxygen electrode was 5 mg/cm<sup>2</sup>.

The electrochemical characterizations were carried out using Swagelok type cell witch components consisting of a nickel foam as the cathode current collector and a lithium metal foil as anode. A commercial electrolyte solution of 1 mol/L LiPF<sub>6</sub> in a mixture of mass fraction of ethylene carbonate (EC)/dimethyl carbonate (DMC) 1:1 was impregnated into membrane as separator and sandwiched between a lithium metal anode and oxygen cathode.

The cells were tested in a sealed oxygen chamber under oxygen flow, and the oxygen pressure was maintained at normal pressure. The cell was cycled in Neware battery test system BTS-XWJ-6.44S-00052 (Newell, Shenzhen, China) with a voltage range of 2.0-4.5 V (vs Li<sup>+</sup>/Li) at different current densities, which can control the test conditions such as the voltage, current, capacity and time of the charge and discharge.

#### **3 Results and discussion**

The nitrogen adsorption/desorption isotherms at 77 K for HPCs marked with HPCs-1, HPCs-2, HPCs-3, HPCs-4, respectively, are shown in Fig. l(a). As shown in Fig. 1(a), all isotherms are type IV isotherm according to the IUPAC classification [31]. High adsorption of nitrogen occurs in the low relative pressure  $(p/p_0)$  range, and obvious hysteresis is detected, suggesting the existence of micro-pores and meso-pores in HPCs [31]. A hysteresis between adsorption and desorption branches can be observed at medium relative pressure (0.4-1.0), which demonstrates the presence of a large number of

Fig. 1 Nitrogen adsorption/desorption isotherms of HPCs at 77 K (a) and whole (b) and local (c, d) pore size distribution of HPCs

mesopores. Furthermore, the isotherms rise sharply at relative pressure  $p/p_0$  close to 1, which reveals the existence of macro-pores. Apparently, the as-prepared porous carbon materials are a combination of micro-, meso- and/or macro-pores with multimodal pore size distribution. The BET surface area, pore size and total pore volume of HPCs are summarized in Table 1. It can be known from Table 1 that the Brunauer-Emmett-Teller (BET) surface areas of HPCs are 539, 546, 691, and 535 m<sup>2</sup>/g for HPCs-1, HPCs-2, HPCs-3, and HPCs-4, respectively; whereas the meso-pores volumes are 0.31, 0.34, 0.39, and 0.35  $\text{cm}^3/\text{g}$  for the above corresponding materials. Besides, it can be found that the concentration of CTAB may also affect the meso-pores volume of the samples. When the concentration of CTAB is less than 0.27 mol/L, there are few meso-pores in the materials; when the concentration of CTAB is more than 0.27 mol/L, with the increase of CTAB the meso-pores volume in the materials may collapse and gradually convert into macro-pores in the carbonization process. Thus, the HPCs-3 has the largest specific surface area and meso-pore volume among all the HPCs. It may be probably attributed to the synergistic effect of dual-template when the concentration of CTAB is 0.27 mol/L [27].

 Table 1 Pore structure characteristics of HPCs prepared under different conditions

Sample	$c(CTAB)/(mol \cdot L^{-1})$	$\frac{S_{\text{BET}}}{(\text{m}^2 \cdot \text{g}^{-1})}$	Pore size/ nm	$V_{\text{total}}/$ (cm <sup>3</sup> ·g <sup>-1</sup> )	$V_{\text{meso}}/$ (cm <sup>3</sup> ·g <sup>-1</sup> )
HPCs-1	0	539	3.80	0.76	0.31
HPCs-2	0.14	546	3.81	0.66	0.34
HPCs-3	0.27	691	3.84	0.60	0.39
HPCs-4	0.41	535	3.79	0.65	0.35

The pore volumes and pore size distribution curves of HPCs which are determined by BJH method are clearly illustrated in Fig. 1(b). The pore size distribution curves are centred in the same pore diameter range, indicating that all porous carbon samples are mainly meso-porous structure and possess similar pore size and pore size distribution. The pores size is between 3.79 and 3.84 nm. Comparatively, HPCs-3 primarily consists of meso-pores.

The surface morphology of HPCs-3 was characterized by FE-SEM and TEM, and the typical results are shown in Fig. 2. The network structure of the HPCs-3 is evidently displayed in Figs. 2(a) and (b). TEM observations were conducted to study the porous textures of the framework walls with representative areas, as

Fig. 2 FE-SEM (a, b) and TEM (c, d) images of HPCs-3

shown in Figs. 2(c) and (d). It can be observed that HPCs-3 consists of numerous macro-pores (Figs. 2(a) and (b)), which are open holes, and a lot of meso-pores distribute on the wall of macro-pores (Figs. 2(b) and (d)). When the macro-pore cores extend into the particles, they can form ion-transport path. As soon as the macro-pore cores are immersed in the electrolyte, the walls of the pore are fully covered by electrolyte, thus giving a shorter diffusion path. Also, the meso-pores can facilitate  $O_2$  diffusion, leading the electrolyte ions to transport into the bulk of material quickly and also providing enough large volume for the discharged products.

The electrochemical performance of HPCs as oxygen electrode of lithium oxygen cell was investigated. Figure 3 shows the discharge behavior of lithium oxygen cells using various HPCs as oxygen electrodes at a constant current density 0.10 mA/cm<sup>2</sup> and in the voltage range of 2.0-4.5 V at room temperature. As seen from Fig. 3, all the curves show smooth and monotonous profiles. The HPCs based oxygen electrodes exhibit excellent electrochemical performance, especially the HPCs-3 owns the highest initial discharge capacity of 2050 mA·h/g. Obviously, the HPCs-3 reveals better performance due to its highest meso-pore volume and specific surface area [5]. This is likely due to the increase in storage space available for the accommodation of discharge product Li<sub>2</sub>O<sub>2</sub> [21]. The discharge process is considered to cease when the pores are choked with discharge product. Therefore, the relatively low discharge capacities associated with samples of lower

Fig. 3 Initial discharge curves of HPCs at current density of  $0.10 \text{ mA/cm}^2$ 

pore volumes are due to a reduced amount of available space for storage of discharge product [32].

The initial open circuit voltages of the cell for different HPCs as oxygen electrodes vary in the range of 3.0-3.2 V (Fig. 3). These values are higher than the theoretical voltage of 2.96 V calculated by the thermodynamics of the reaction of Li and O<sub>2</sub> to form Li<sub>2</sub>O<sub>2</sub> [33]. Higher open circuit voltage of the cell compared with the theoretical voltage may be due to a mixed potential effect associated with reaction of Li ions and impurities in the electrolyte [34].

Decrease of capacity with the increase of current density is currently another serious issue for lithium oxygen battery. In order to assess the power capabilities of the lithium oxygen cells, the electrochemical performance of the cells was analyzed at different discharge rates. As shown in Fig. 4, the cell using HPCs-3 as oxygen electrode delivers a specific capacity of 2667 mA·h/g at a low current density of 0.05 mA/cm<sup>2</sup>. However, the specific capacity and operating voltage drop significantly with the increase of current density. The discharge capacities of HPCs-3 oxygen electrode at different discharge current densities are 2667, 2050, 1206, 607 mA·h/g, at discharge currant density of 0.05, 0.10, 0.20 and 0.50 mA/cm<sup>2</sup> respectively. The HPCs-3 exhibits a relatively poor rate capability. The inherent limitation of lithium oxygen battery, the limited oxygen solubility and diffusivity significantly affect the rate capability of the cell since there is no enough oxygen to enable the discharge reaction at a high current density [28].

Fig. 4 Discharge curves of HPCs-3 at different discharge rates

The cycle performance of the lithium oxygen cell using HPCs-3 as oxygen electrode is shown in Fig. 5. In the case of deep discharge with a cut-off voltage of 2.0 V, a relatively high initial discharge capacity of about 2050 mA·h/g was obtained (Fig. 5(a)); however, the capacity retention remains rather poor with the discharge capacity dramatically dropping to 670 mA·h/g after 10 cycles. The poor capacity retention of the cell could be attributed to the continuous rise of resistance which results from

Fig. 5 Cycle performance of lithium oxygen cells in condition of deep discharge (a) and only restricting charge/discharge capacity to 800 mA-h/g (b)

the aggregation of discharge product. By avoiding deep discharge and restricting discharge capacity only to 800 mA·h/g, the cell exhibits a good capacity retention after 10 cycles. As shown in Fig. 5(b), it is nearly a horizontal line after the 10th cycle. It may be ascribed to the problem settled that pores can be easily choked by discharge product [35]. In this condition, even if the electrode expands, the electrical contact between the active materials and current collector is still good. Moreover, Li<sub>2</sub>O<sub>2</sub> and Li<sub>2</sub>O decomposition during the charge process renews the porosity and makes further cycle possible.

#### 4 Conclusions

1) Various HPCs with meso-porous structure were successfully synthesized by self-assembly process via adjusting surfactant concentration.

2) All of the synthesized HPCs mainly possess meso-porous structure with similar pore size distribution. Especially, the HPCs-3 prepared at c(CTAB)=0.27 mol/L shows the largest mespores volume of 0.35 cm<sup>3</sup>/g, and the highest discharge capacity of 2050 mA·h/g at the current density of 0.10 mA/cm<sup>2</sup>.

3) The discharge capacity of the lithium oxygen battery using HPCs as air electrode will be improved with the increasing specific surface area at nearly same pore size. Besides, the lithium air battery exhibits a good capacity retention through controlling discharge depth to  $800 \text{ mA}\cdot\text{h/g}$ .

4) Although the rate capability of HPCs-3 air electrode needs to be further improved, it will be a kind of promising air electrode for the application of lithium oxygen batteries.
