Received 12 January 2015; accepted 28 December 2015

Abstract: The oxidative dissolution of metalliferous black shale in sulfuric acid solution using sodium persulfate as an oxidant was investigated. The effects of leaching factors including leaching temperature, leaching time, stirring speed, initial concentration of sodium persulfate and sulfuric acid and particle size on the leaching rate were studied as well. The leaching kinetics of molybdenum, nickel and iron from metalliferous black shale shows that the leaching rate is controlled by a chemical reaction through a layer on the unreacted shrinking core. The leaching process follows the kinetics model $1-(1-a)^{1/3}=kt$ with apparent activation energies of 34.50, 43.14 and 71.79 kJ/mol for Mo, Ni and Fe, respectively. The reaction orders in sodium persulfate are 0.80, 1.01 and 0.75 for molybdenum, nickel and iron, respectively, while in sulfuric acid, these orders are 0.45, 0.75 and 0.50 for molybdenum, nickel and iron, respectively. In addition, the reaction mechanism for the dissolution of the metalliferous black shale was discussed. **Key words:** metalliferous black shale; oxidative leaching; kinetics; sodium persulfate

1 Introduction

Nickel and molybdenum have strategic and industrial importance owning to their applications in many technological fields [1,2].

Metalliferous carbonaceous shales are organic-rich rocks that contain economically significant concentration of metals such as Mo, Ni and V [3–5], namely, these carbonaceous shales are also called Ni–Mo ores. These Ni–Mo ores are found mainly in South China, such as Zhangjiajie, Fuyang, Zunyi and Eastern Yunnan Province [5–7]. Several studies have been elaborated that the chemical composition of molybdenum can be written as the chemical formula of MoS_2 in the ores, but it is different from molybdenite. The MoS_2 in black shale exists amorphously compared with molybdenite, and the mole ratio of S to Mo is about 2.1-2.5 since there are some impurities such as MoS₃, and combination of organic carbon, clay and quartz [8]. In addition, the occurrence states of nickel in the ores are various, such as NiS₂, NiS, Ni₃S₄ and NiAsS [9,10]. Nickel and molybdenum all exist in an amorphous phase form [4,11].

In the past years, several mineral processes have been tested for treating Ni–Mo ore, such as flotation separation, gravity separation combined with flotation [12,13]. However, owing to its complex mineralogical characteristics and low metals recovery, the application of mineral dressing methods does not suit for the separation and recovery of nickel and molybdenum from Ni–Mo ore. For these reasons, researchers have to resort to the direct metallurgical processes for treating Ni–Mo ore.

In recent years, many methods, such as direct alkaline leaching with hypochlorite [14] or oxygen [8,15] condition, and roasting followed by mixed alkali leaching with NaOH/Na₂CO₃ [16], have been used to leach molybdenum from the Ni–Mo ores. These extraction processes have been successfully used for commercial operations in China with high molybdenum extraction; however, nickel still remains in the leach residue cake, which needs to be recovered. Although the extraction of molybdenum and nickel from carbonaceous shale was investigated by oxidation roasting, sulphate roasting and water leaching [4], the high operating cost for roasting and the high capital cost for absorbent vessels of SO₂ make the cost of the metallurgical process of Ni–Mo ore prohibitively expensive.

Acid has been investigated for leaching nickel and molybdenum from Ni–Mo ore with oxidants. ZHANG et al [17] and XIAO et al [18] investigated the dissolution of nickel and molybdenum from Ni–Mo ore in acid solution with oxidants, respectively. All of these results indicate that the extraction efficiency of molybdenum is less than 70 % in HCl [17] or HNO₃[18] solution with oxidants.

In a word, it is necessary to develop a novel metallurgical process for the dissolution of Ni–Mo ore. The process could be characterized as being environment-friendly and may be high extraction efficiency of nickel and molybdenum at low-cost.

The aim of this work is to investigate a simple leaching process for the relatively low grade No–Mo ore materials from Xiangxi region in Hunan Province, China, by using H_2SO_4 acid in the presence of $Na_2S_2O_8$ as an oxidant. This work considers the oxidative leaching kinetic about the Ni–Mo ore. The effects of the main system variables on the leaching rate were examined and the kinetic model and the apparent activation energy were determined.

2 Experimental

2.1 Materials

The Ni–Mo ore was collected from Xiangxi region in Hunan Province, China. The sample was firstly crushed to 2 mm and then ground to the required particle size of fraction ranges 75–80, 90–96, 120–125, 160– 180 µm. To identify the mineral composition of the collected Ni–Mo ore, both the bulk and sieved samples were subjected to X-ray diffraction (XRD) analysis. The result of XRD is presented in Fig. 1. It indicates that there are five crystalline phases, namely, quartz (SiO₂), pyrite (FeS₂), fluorapatite (Ca₅(PO₄)₃F), calcite (CaCO₃) and epidote (Ca₂Al_{2.6}Fe_{0.4}Si₃O₁₃H) in the Ni–Mo ore. As seen from Fig. 1, the crystal mineral phases of molybdenum and nickel are not identified, which means that both metals may exist as amorphous phases in the Ni–Mo ore. This result agrees well with those results obtained by several researchers [4,11].

The raw ore and the different size fractions were analyzed for their major and minor elements using the reported methods [19], the results of major constituents are listed in Table 1 and the results of minor valuable elements are followed as: 0.161% Pb, 0.085% K, 0.081% Co, 0.082% Na, 0.032% Cu, 0.034%Ti, 0.028% Cr, 0.025% Se, 0.022% Mn, 0.008% Y, 0.005% Sr and 0.001% Zr. The analysis of nickel and iron was performed by an inductively coupled plasma emission spectroscopy (ICP) with а PS-6 PLASMA SPECTROVAC, BAIRD (USA), whereas molybdenum was determined with ammonium thiocyanate colorimetry by spectrophotometer [20]. The mineralogical analyses of molybdenum in the Ni-Mo ore were assayed by chemical phase analyses [21] and the results showed that that molybdenum occurred as 80.7 % MoS₂ and 19.3 % MoO₃. LIU et al [22] also claimed that molybdenum in Ni-Mo ores existed as MoS₂ and MoO₃.

2.2 Methods

In each experiment, a flask containing 500 mL leaching solution of the desired concentrations of sulfuric acid and sodium persulfate, was submerged in a tank, the temperature was kept constant with ± 0.1 K (0.1 °C). When the desired temperature was reached, 10 g Ni-Mo ore was added and the mechanical stirring started and kept at a certain stirring speed. The leaching was performed for 3 h during which 2 mL sample of the solution was taken for the determination of Mo, Ni, Fe concentrations at interval time. Molybdenum was determined with ammonium thiocyanate colorimetry by spectrophotometer. Nickel and iron, were assayed by an inductively coupled plasma emission spectroscopy (ICP). After leaching, the residue was filtered and then the leached cake was dried for 8 h at 373.15 K (100 °C). The phase of the leaching residue was characterized by a Max-Ra X-ray diffractometer.

3 Results and discussion

3.1 Effect of different oxidants on extraction of metals from Ni-Mo ore

In Ni–Mo ores, the molybdenum and nickel mainly occur as sulfides including MoS_2 , NiS_2 , NiS, Ni_3S_4 and NiAsS. These sulfides cannot be dissolved in acidic solution without oxidants. Therefore, the purpose of adding oxidants is to oxidize sulfides and to extract metals easily.

The experiments for leaching Ni-Mo ore with different oxidants including sodium persulfate, sodium chlorate and hydrogen peroxide were performed in the conditions of reaction time 3 h, temperature 358.15 K (85 °C), stirring speed 600 r/min, liquid-to-solid ratio 50 mL/g and initial concentration of sulfuric acid 0.5 mol/L. Initial concentration of oxidant 0.5 mol/L was used for the oxidative leaching of Ni-Mo ore. The extraction rate of metals is presented in Fig. 2. As seen from Fig. 2, the oxidation capacity order of these oxidants is Na₂S₂O₈>NaClO₃>H₂O₂. At the same time, it is observed that the extraction rate of metals using sodium persulfate as an oxidant is higher than that of metals with other oxidants. It can be explained that the standard reduction potential of persulfate ($E^{\Theta}=2.01$ V) is higher than that of NaClO₃ (E^{Θ} =1.45 V) and H₂O₂ $(E^{\Theta}=1.77 \text{ V})$. However, the oxidation capacity of H₂O₂ is less than that of NaClO₃ in the oxidative leaching process because H₂O₂ is decomposed easily into O₂ and H₂O at 358.15 K (85 °C), and the sulfides in the Ni-Mo ore are not enough to be oxidized owing to O₂ escaping easily from the solution. Simultaneously, it may be explored that the extraction of Mo in acid solution with other oxidants reported in some literatures [17,18] is lower than that of Mo in acid solution with persulfate.

The advantage of sodium persulfate as a lixiviant in sulfuric acid solutions is that it can be made from sulfuric acid using an electrochemical cell [23]. The energy cost for making persulfate from sulfuric acid are 0.20 \$/kg [24]. Once the persulfate reacts, it can return back to sulfate ions that can be converted back to persulfate. Thus, there is no consumption of the sulfuric acid used in leaching process. Therefore, sodium persulfate was determined as the oxidant for oxidative leaching of Ni–Mo ore.

Fig. 2 Effect of different oxidants on extraction of metals in Ni-Mo ore

3.2 Phase changes and morphology during oxidation leaching

After comparison of XRD patterns in the residues with the raw Ni–Mo ore, it can be observed that calcite disappeared in the residues and all pyrite, fluorapatite and epidote disappeared in the residues after leaching for 3 h. At the same time, a new crystal phase anhydrite (CaSO₄) occurred in the residues. This indicates that the dissolution reactions of calcite, epidote, fluorapatite should be expressed by the following equations:

$$CaCO_3 + H_2SO_4 = CaSO_4 + CO_2 + H_2O$$
(1)

$$2Ca_{2}Al_{2.6}Fe_{0.4}Si_{3}O_{13}H+13H_{2}SO_{4}=$$

$$4CaSO_{4}+0.8Fe^{3+}+6SiO_{2}+14H_{2}O+5.2Al^{3+}+9SO_{4}^{2-}$$
(2)

$$Ca_{5}(PO_{4})_{3}F+5H_{2}SO_{4}=5CaSO_{4}+3H_{3}PO_{4}+HF$$
(3)

and then SiO₂ with HF may take reaction as follows:

$$SiO_2 + 6HF = H_2SiF_6 + 2H_2O$$
(4)

The SEM-EDS of the leaching residue whose raw was ranged from 90 to 96 μ m sample is shown in Fig. 3. It indicated that the micrograph of the leaching residues indicates a progressive increase in the roughness of the solid. After 60 min leaching, the particles present some degree of degradation, which gradually increases along the progress of leaching to 180 min (Fig. 3(b)). The EDS of micro areas 1 and 2 for the residue shows that sulfur and silicon assemble onto the mineral surface. At the

Fig. 3 SEM images of raw ore (a) and residue (b) and EDS results of areas 1 (c) and 2 (d)

same time, a new phase elemental S in the residues occurs by XRD method. The results obtained from the SEM–EDS and XRD of the residue show that the elemental sulfur is formed from the oxidation of the sulfide ores in acidic solution containing persulfate. It was reported that elemental sulfur can exist in acidic solution containing persulfate [25] and that elemental sulfur is very stable below 393 K in acid solution under an oxygen pressure and above this temperature is oxidated into SO_4^{2-} where the rate of oxidation reaction of elemental sulfur increases rapidly with temperature [26]. This indicates that the sulfides in the Ni–Mo ore may take reactions as follows:

$$MoS_2 + 3S_2O_8^{2-} + 4H_2O = MoO_4^{2-} + 8H^+ + 6SO_4^{2-} + 2S$$
 (5)

$$NiS_2 + S_2O_8^{2^2} = Ni^{2^+} + 2SO_4^{2^-} + 2S$$
(6)

$$NiS + S_2 O_8^{2^-} = Ni^{2^+} + 2SO_4^{2^-} + S$$
(7)

$$Ni_{3}S_{4}+3S_{2}O_{8}^{2-}=3Ni^{2+}+6SO_{4}^{2+}+4S$$
(8)

$$2NiAsS+7S_2O_8^{2-}+8H_2O=$$

 $2Ni^{2+}+14SO_4^{2-}+2AsO_4^{3-}+2S+16H^+$ (9)

 $FeS_2 + S_2O_8^{2-} = Fe^{2+} + 2SO_4^{2-} + 2S$ (10)

$$2Fe^{2+}+S_2O_8^{2-}=2Fe^{3+}+2SO_4^{2-}$$
(11)

3.3 Effect of stirring speed on leaching of Ni-Mo ore

The effect of the stirring speed was studied under these conditions of reaction time 3 h, temperature 358.15 K (85 °C), liquid-to-solid ratio 50 mL/g and

initial concentrations of sulfuric acid 0.5 mol/L and sodium persulfate 0.5 mol/L. The ranges of stirring speeds were 150, 300, 450, 500, 550, 600 and 700 r/min. The leaching rates for molybdenum, iron and nickel increased as the stirring speed was increased to 600 r/min and remained almost constant above 600 r/min. Therefore, the optimum speed 600 r/min was used for all subsequent tests.

3.4 Effect of temperature on leaching of Ni-Mo ore

The leaching experiments were carried out with the particle size of 90-96 µm in the temperature range of 338.15-368.15 K for initial concentrations of sulfuric acid 0.5 mol/L and sodium persulfate 0.5 mol/L. The influence of temperature on the extraction of molybdenum is shown in Fig. 4. It indicates that the extraction of molybdenum increases with the temperature increasing. The change of temperature from 338.15 K to 368.15 K increases the extraction efficiency of molybdenum from 62.3 % to 98.6 %. The summarized results of the investigated metal extraction after leaching for 3 h are presented in Fig. 5. The influence of temperature on the leaching efficiency is very obvious for Mo, Ni, and Fe. An increase in temperature from 338.15 K to 368.15 K causes an increase in Ni and Fe extraction from 82.2% to 96.5% and 75.6% to 93.4%, respectively.

Fig. 4 Effect of temperature on molybdenum extraction

Fig. 5 Effect of temperature on Mo, Ni and Fe extraction

To control the leaching process, it is important to establish a quantitative measurement of the leaching kinetics and mechanism. The slowest step controls the whole leaching kinetics and is regarded as the rate-limiting step. The experimental data were analyzed using several models contenting the fraction reacted (a) and time (t) [27]. The two model were applied.

Spherical particles under a product layer diffusion control:

$$1 - 2/3a - (1 - a)^{2/3} = k_{\rm d}t \tag{12}$$

Spherical particles under control of chemical reaction through a layer on the unreacted shrinking core:

$$1 - (1 - a)^{1/3} = k_c t \tag{13}$$

where $k_d = c/d_0^2$ and $k_c = c/d_0$ are the pore diffusion rate constant and the chemical rate constant, respectively, *c* is constant, *t* is the leaching time and d_0 denotes the initial particle diameter.

Among two kinetics models tested, only Eq. (13) has been found to give a perfect straight line with a good correlation.

The plot of the data from Fig. 4 for molybdenum

according to Eq. (13) versus time (t) is presented in Fig. 6(a). The values of correlation coefficients (R^2) for other examined metals are summarized in Table 2. As is seen, during the whole leaching time, the data in Fig. 6(a) and Table 2 linearly change with temperature, which indicates that the reaction rate is controlled by the chemical reaction through a layer on the unreacted shrinking core. This result obtained is different from that of the oxidative–alkaline leaching of molybdenum in the metalliferous black shale which was controlled by diffusion with the activation energy of 15 kJ/mol at higher than 338.15 K [28].

Fig. 6 Plot of date in Fig. 4 according to Eq. (13) (a) and Arrhenius plot for leaching of molybdenum (b)

Table 2 Values of correlation coefficients (R^2) of metals leaching from Ni–Mo ore in solution of 0.5 mol/L H₂SO₄ and 0.5 mol/L Na₂S₂O₈ depending on temperature

Tomporaturo/V	Correlation coefficient (R^2)						
Temperature/K	Ni	Мо	Fe				
338.15	0.991	0.991	0.993				
348.15	0.998	0.989	0.996				
358.15	0.995	0.996	0.995				
368.15	0.993	0.987	0.992				

To determine the activation energy (E_a) , the plot of ln k against 1/T should be a straight line with a slope of $-E_a/R$ and the intercept of ln A, according to the Arrhenius equation:

$$\ln k = \ln A - E_a / (RT) \tag{13}$$

where k is the apparent rate constant, A is the pre-exponential factor, R is the mole gas constant and T is the thermodynamic temperature.

The apparent rate constant k (see Table 3), obtained from the slops of the straight lines in Fig. 6(a) (for molybdenum) was used to determine the activation energy of 34.50 kJ/mol, as given on the Arrhenius plot in Fig. 6(b). Similarly, the activation energies for Ni and Fe were obtained, and the calculated values were 43.14 kJ/mol and 71.79 kJ/mol, respectively.

Table 3 Values of apparent rate constant of metals leaching from Ni–Mo ore in solution of 0.5 mol/L H_2SO_4 and 0.5 mol/L $Na_2S_2O_8$ depending on temperature

Tours and my /V	$k/10^3 \mathrm{min}^{-1}$					
Temperature/K	Мо	Fe	Ni			
338.15	2.08	2.51	1.53			
348.15	3.29	5.62	2.40			
358.15	4.42	11.01	3.80			
368.15	5.79	20.02	5.21			

The magnitudes of activation energies found in this study support the theory that the chemical reaction is the rate-limiting step of dissolution process. Furthermore, these activation energies are close to the following calculated activation energy values: 40.40 kJ/mo1 for molybdenite in sulfuric acid solution containing hydrogen peroxide [29] and 68.8 kJ/mo1 for molybdenite in nitric acid solution under high pressure [30], 39.67 kJ/mo1 for nickel sulfide dissolution by sodium persulfate in acidic solution [25] and 83 kJ/mol for pyrite (FeS₂) leaching in acidic ferric sulfate media [31].

3.5 Effect of initial concentration of sodium persulfate on leaching of Ni-Mo ore

These experiments were performed in the presence of different initial concentrations of Na₂S₂O₈ varying from 0.30 to 0.60 mol/L. The other leaching conditions were fixed at temperature of 358.15 K, reaction time of 3 h, a liquid/solid ratio of 50 mL/g and an ore size of 90–96 µm. The results for molybdenum are shown in Fig. 7. The corresponding plots of $1-(1-a)^{1/3}$ versus time for molybdenum at various initial concentrations of Na₂S₂O₈ are graphed in Fig. 8(a). The summarized results of the metal extraction leaching for 3 h are presented in Fig. 9 at different concentrations of Na₂S₂O₈ from

Fig. 7 Effect of initial concentration of $Na_2S_2O_8$ on molybdenum extraction

Fig. 8 Relationship between $[1-(1-a)^{1/3}]$ and leaching time for molybdenum leaching at various Na₂S₂O₈ concentrations (a) and plot of rate constant versus Na₂S₂O₈ concentration for molybdenum (b)

0.30 to 0.50 mol/L causes an increase in molybdenum, nickel and Fe extractions from 79.2% to 93.6%, 81.5% to 90.8% and 68.5% to 89.7%, respectively. The extractions of Mo, Ni and Fe have no significant change even when the $Na_2S_2O_8$ concentration further increases. Therefore, initial concentration of $Na_2S_2O_8$ 0.50 mol/L was chosen for the subsequent experiments.

Fig. 9 Effect of $Na_2S_2O_8$ concentration on extraction of Mo, Ni and Fe

In order to obtain the reaction order of the total $Na_2S_2O_8$ concentration for molybdenum, $lnc(Na_2S_2O_4)$ lnk plot of the rate constants versus the total $Na_2S_2O_8$ concentration is plotted in Fig. 8(b). The slope of the line, or the reaction order of the total $Na_2S_2O_8$ concentration for molybdenum, is 0.801. Similarly, the reaction orders of the total $Na_2S_2O_8$ concentration for Ni and Fe according to the experimental data were calculated to be 1.01 and 0.75, respectively.

3.6 Effect of initial concentration of sulfuric acid on leaching of Ni-Mo ore

A series of leaching experiments were performed using different H_2SO_4 concentrations. The other leaching conditions were fixed as follows: initial concentration of $Na_2S_2O_8$ 0.50 mol/L, liquid-to-solid ratio of 50 mL/g, an ore size of 90–96 µm, temperature 358.15 K. The influence of H_2SO_4 concentration on the extraction of molybdenum is shown in Fig. 10. It is clear that the extraction of molybdenum increased with the initial concentration of H_2SO_4 increasing. The extraction of

Fig. 10 Effect of H_2SO_4 concentration on molybdenum extraction

molybdenum increased from 93.2 % to 98.69 % when the initial concentration of H_2SO_4 increased from 0.50 to 1.10 mol/L. The summarized results of the metal extraction after leaching for 3 h are presented in Fig. 11 at different H_2SO_4 concentrations. An increase in initial concentration of H_2SO_4 from 0.50 to 1.10 mol/L causes an increase of Ni and Fe extractions from 90.7% to 97.2% and 89.6% to 94.6%, respectively.

Fig. 11 Effect of initial concentration of H_2SO_4 on extraction of Mo, Ni and Fe

The corresponding plots of $1-(1-a)^{1/3}$ versus time (*t*) for molybdenum at various concentrations of H₂SO₄ are graphed in Fig. 12(a). In order to obtain the reaction order of the total H₂SO₄ concentration for molybdenum, ln $c(H_2SO_4)$ -ln k plots of the rate constants versus the total H₂SO₄ concentration are plotted in Fig. 12(b). The slope of the line, or the reaction order of the total H₂SO₄ concentration for molybdenum, is 0.45. Similarly, the reaction orders of the total H₂SO₄ concentration for Ni and Fe according to the experimental data were calculated to be 0.70 and 0.50, respectively.

3.7 Effect of particle size on leaching of Ni-Mo ore

The influence of particle diameter on the extraction of metals was examined by measuring the reaction rate for fractions of four sizes: 75–80, 90–96, 120–150, 160–180 µm in a solution containing 0.5 mol/L H₂SO₄ and 0.5 mol/L Na₂S₂O₈ at 358.15 K with a leaching time of 150 min. The results for nickel are given in Fig. 13. As expected, the smaller the particle sizes, the faster the extraction of metals. After being ground, the spherical shape of the grains of the Ni–Mo ore was obtained. As a result, description of the kinetic curves for chemical reaction control model based on the spherical grains was found to be suitable for this purpose $(1-(1-a)^{1/3}=kt)$.

The data from Fig. 14 for nickel were analyzed according to Eq. (13). The data presented in Fig. 14(a) and the calculated apparent rate constants are plotted

Fig. 12 Relationship between $[1-(1-a)^{1/3}]$ and leaching time for molybdenum leaching at various H₂SO₄ concentrations (a) and plot of rate constant versus H₂SO₄ concentration (b)

Fig. 13 Effect of particle size on nickel extraction

versus the inverse of the initial particle diameter d_0 (Fig. 14(b)). The linear relationship between the rate constant k and the inverse of d_0 indicates that the chemical reaction through a layer on the unreacted shrinking core is indeed the rate-limiting step of the dissolution process.

Fig. 14 Plot of variation of $1-(1-a)^{1/3}$ with time for various particle diameters (a) and rate constant versus initial particle diameter d_0 of Ni–Mo ore (b)

4 Conclusions

1) The dissolution kinetics of Ni–Mo ore was investigated in acid solution with sodium persulfate. The effects of leaching factors including leaching time, temperature, stirring speed, particle size, initial concentration of sulfuric acid and initial concentration of these oxidants such as $Na_2S_2O_8$, $NaClO_3$ and H_2O_2 were studied as well.

2) The oxidation capacity order of these oxidants is $Na_2S_2O_8>NaClO_3>H_2O_2$ on the leaching of Ni–Mo ore and sodium persulfate is chosen to be the oxidant for leaching Ni–Mo ore. The influence of temperature on the leaching Ni–Mo ore is very obvious in the cases of Mo, Ni and Fe.

3) The leaching process follows the kinetics model $1-(1-a)^{1/3}=kt$. The values of the apparent activation energies of 34.50, 43.14 and 71.79 kJ/mol for Mo, Ni and Fe, respectively, support the conclusion that the dissolution rate is controlled by the chemical reaction through a layer on the unreacted shrinking core.

4) The reaction orders in sodium persulfate are 0.80, 1.01 and 0.75 for Mo, Ni and Fe, respectively, while in the sulfuric acid these orders are 0.45, 0.75 and 0.50 for Mo, Ni and Fe, respectively.

摘 要:研究金属黑色页岩在过硫酸钠酸性溶液中的氧化浸出行为。考察了反应温度、浸出时间、搅拌速度、过 硫酸钠和硫酸的浓度、矿物颗料的尺寸等因素对氧化浸出速度的影响。结果表明:黑色页岩中钼、镍和铁的浸出 行为受化学反应速度控制,浸出过程的动力学模型为1-(1-a)^{1/3}=kt,且钼、镍及铁的表观活化能分别为34.50,43.14 和71.79 kJ/mol;对于过硫酸钠,钼、镍和铁的反应级数分别为0.80,1.01和0.75;对于硫酸,钼、镍和铁反应 级数分别为0.45,0.75和0.50。此外,对金属黑色页岩的溶解反应机理进行了探讨。 关键词:金属黑色页岩;氧化浸出;动力学;过硫酸钠
