Received 15 July 2007; accepted 10 September 2007

**Abstract:** Iron polymeric hydroxygroups pillared clays (Fe-PILC) were prepared by  $\text{Na}^+$ -montmorillonite with iron pillarating agent. 2.01Au/Fe-PILC catalyst was obtained by deposited-precipitation (DP) method. 2.52Au/Fe-oxide catalyst was prepared by co-precipitation method. The catalytic activity of these catalysts was measured by catalytic combustion of formaldehyde. The catalyst of 2.01Au/Fe-PILC exhibits the high catalytic activity. The catalytic combustion reaction of formaldehyde proceeds at considerable rates at 20 °C and complete burn-off of formaldehyde is achieved at 120 °C. The structure of catalysts, the valence state of gold and the size of gold particles were investigated by means of X-ray powder diffractometry, X-ray photoelectron spectroscopy and transmission electron microscopy. The results show that gold atoms with partially positive charge exist in the catalyst and play an important role in the catalytic activity. In addition, nano-sized, well-dispersed gold particles and good adsorption properties of support are necessary to obtain high activity Au catalysts for catalytic combustion of formaldehyde.

**Key words:** Au/Fe-PILC catalyst; catalytic combustion of formaldehyde; gold with positive charge; gold nanocrystals

### 1 Introduction

Formaldehyde (HCHO) is a common indoor contaminant which is widely used in the production of isolation materials, furniture, disinfectants, water-based paints (as additive), and exists in tobacco smoke, exhaust gases and even wood. Chronic exposure to the air polluted by HCHO with low concentration may cause adverse effects on health, such as skin disease, tracheitis and even lung cancer. In general, the techniques for the removal of the low concentration HCHO can be classified into two major classes: recycling and combustion of the formaldehyde[1–2]. Although it is technically feasible for the recycling of the low concentration HCHO, it is not an economic approach. Accordingly, catalytic combustion at relatively low temperature appears to be the potential solution for this environmental problem by virtue of its low energy cost.

Noble metals usually exhibit superior catalytic activity for the removal of formaldehyde/methanol[3].

However, noble metals are expensive and vulnerable to poisoning and the applications of these catalysts in commercial scale have been seriously impeded by these serious concerns. Some metal oxides[4] and transition metal perovskites[5] were investigated as substitutes for the noble metals, but their activities for catalytic combustion were unsatisfactory. Consequently, developing new catalysts, which do not contain noble metals and are able to catalyze the HCHO at moderate temperatures, is vital for HCHO combustion technique.

Naturally existing montmorillonite clays are layered alumni-silicates, which are held together by weak electrostatic force. New classes of materials have been recently developed by exchanging the small  $\text{Na}^+$  ions that are normally found between these layers with inorganic metal ions of larger size and charge, such as iron, complexes, etc[6]. Fe-PILC was adapted because of good properties on catalysis and adsorption, which is few publicly reported.

In the present work, active species gold was supported by deposited-precipitation (DP) method. The

catalytic activity of Au/Fe-PILC and Au/Fe-oxide catalysts for catalytic combustion of formaldehyde was measured.

## 2 Experimental

### 2.1 Catalyst preparation

Smectite used in this work came from Inner Mongolia, China. Ca-montmorillonite was obtained after washing, removing excess salt, centrifuging and drying. Then Ca-montmorillonite (10 g) was dispersed in 0.5 mol/L Na<sub>2</sub>CO<sub>3</sub> solution (1 L) for 5 h at 65 °C in order to exchange Na<sup>+</sup> and get Na<sup>+</sup>-montmorillonite[7].

0.5 mol/L Na<sub>2</sub>CO<sub>3</sub> solution was slowly dipped into 0.1 mol/L Fe(NO<sub>3</sub>)<sub>3</sub> solutions at pH=2.2 [8]. The iron pillaring agent was kept for 24 h at room temperature, then dipped into 1% Na<sup>+</sup>-montmorillonite (pH=9.5). Through dispersing and washing, Fe-PILC was obtained. The centrifuged Fe-PILC was separated into two parts. One was used as reference. The other was added into 2.5 mmol HAuCl<sub>4</sub> solution and reacted to get Au/Fe-PILC catalyst after washing, drying and calcination. Au/Fe-oxide catalysts were prepared by a co-precipitation approach[9].

### 2.2 Catalyst characterization

The structures of the catalysts were characterized by X-ray powder diffractometry (XRD, Phillips PW 1700X, Cu K<sub>α</sub>, 40 kV, 20 mA). The morphologies of the catalysts were obtained by transmission electron microscopy (TEM, JEM2010, 120 kV).

The bonding energy were measured by X-ray photoelectron spectroscopy (XPS, VG ESCALAB MK-2, Al K<sub>α</sub>=1 486.6 eV, voltage 12.5 kV, power 250 W, E(C<sub>1S</sub>)=284.6 eV, vacuum 2×10<sup>-8</sup> Pa).

The content of Au was measured by atomic absorption spectroscopy (AAS, Analyst 200 USA). In samples, Au contents were found to be 2.01% and 2.52% (mass fraction), respectively. The catalysts were denoted as 2.01Au/Fe-PILC and 2.52Au/Fe-oxide. The samples without gold were also denoted as reference, named Fe-PILC and Fe-oxide.

### 2.3 Catalytic activity measurement

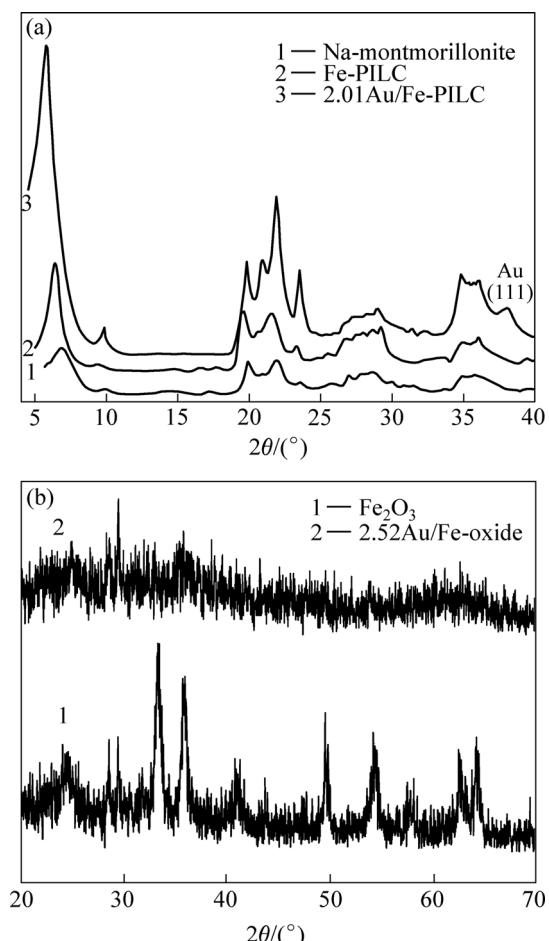

The activity of the catalysts for catalytic combustion of formaldehyde was tested in a conventional continuous flow U-shape glass ( $d = 8$  mm) reactor at atmosphere pressure. Catalyst (0.2 g, 100–175 μm) was loaded. The gaseous reactant mixture was fed to the reactor by an air flow from a cylinder, which passes through a container filled with formalin (37% formaldehyde). In order to keep the temperature of formalin at 0 °C, the formalin container was immersed in a mixture of water and ice. The flow rate passing through the reactor was controlled

at 180 mL/min by a mass-flow meter. This flow rate is equivalent to 6.25 mg/m<sup>3</sup> of formaldehyde. The effluent gases were analyzed on-line by a gas chromatograph (GC-8A, Shimadzu) equipped with thermal conductivity detector (TCD) and packed with GDX-403. Column temperature was 110 °C and TCD detection temperature was 160 °C. Current was kept at 80 mA. Helium was used as carrying gas (30 mL/min) for the GC analysis.

## 3 Results and discussion

### 3.1 Structural features of catalysts

Fig.1 illustrates the XRD patterns for the pillared products and Fe-oxide. The X-ray basal spacings ( $d_{001}$ ) are described in Table 1.

**Fig.1** XRD patterns of 2.01Au/Fe-PILC(a), 2.52Au/Fe-oxide(b) catalysts and some references

**Table 1**  $d_{001}$ -basal spacing values

Sample	2θ/(°)	$d_{001}$ /nm
Na <sup>+</sup> -montmorillonite	7.091	1.25
Fe-PILC	6.995	1.26
2.01Au/Fe-PILC	5.901	1.5

The low  $2\theta$  peak of the basal spacing,  $d_{001}$ , was initially positioned near  $7.091^\circ$ , and the peak was relatively strong, indicating that the effect of sodium exchange montmorillonite was distinguished[10]. The basal spacing of Fe-PILC was equal to that of  $\text{Na}^+$ -montmorillonite. As for 2.01Au/Fe-PILC, the peak of the low  $2\theta$  shifted to higher basal spacing and increased in intensity, which indicated nano-gold particle intercalated into the interlayer. Other major peaks in Fig.1(a) are assigned as follows. The peaks at  $2\theta$  of  $19.6^\circ$  and  $34.9^\circ$  are assigned to the two-dimensional diffraction. Weak peaks of metallic gold ( $\text{Au}^0$ ) at  $2\theta$  values of  $38.2^\circ$  is attributed to diffraction from (111) lattice plane. When gold is loaded in ion states, it is highly dispersed in small size so that its diffraction is too weak to be observed. Fig.1(b) shows the XRD patterns of 2.52Au/Fe-oxide catalyst. From the reference, The high peaks at  $2\theta$  of  $33.36^\circ$  and  $35.79^\circ$  are confirmed to be the phase of  $\text{Fe}_2\text{O}_3$  [11]. When gold was supported, no sharp peaks for either iron oxide or metallic gold could be observed, indicating that their crystal sizes are very small [12–13].

### 3.2 Catalytic activity

Fig.2 and Fig.3 show the TEM photographs and the size distribution of gold particles. The spherical gold nanoparticles were observed as dark spots, which were homogeneously dispersed on the surfaces of Fe-PILC support (Fig.2). The mean particle size of gold was determined in the narrow range of 2–5 nm. While in the 2.52Au/Fe-Oxide sample, the iron oxide component of the catalyst consisted of aggregates of fine particles with sizes up to several tens of nanometers. The mean particle size of gold was determined to be in the range of 10–15 nm (Fig.3).

$\text{CO}_2$  and  $\text{H}_2\text{O}$  were the products of the catalytic HCHO combustion. The experimental results (Fig.4 and Fig.5) indicated clearly that 2.01Au/Fe-PILC catalyst showed excellent catalytic behavior. The burn-off temperature of 2.01Au/Fe-PILC is lower by  $40^\circ\text{C}$  than that of 2.52Au/Fe-Oxide catalyst. Based on TEM image, 2–5 nm gold particles were prerequisite for high-activity gold catalysts[14]. Moreover the Fe-PILC was interlayer support and had much micro pores, which resulted in active species gold homogeneously dispersed on the surfaces of Fe-PILC support and over aggregates of nanogold particles were got. The more the value of  $d_{001}$  is, the better the adsorption is.

### 3.3 Oxidation state of gold

XPS analyses were carried out in order to determine the valence state of gold on 2.01Au/Fe-PILC and 2.52Au/Fe-oxide catalysts. The existing forms and the states of the gold in the catalyst were crucial for explaining the good catalytic activity. It has been

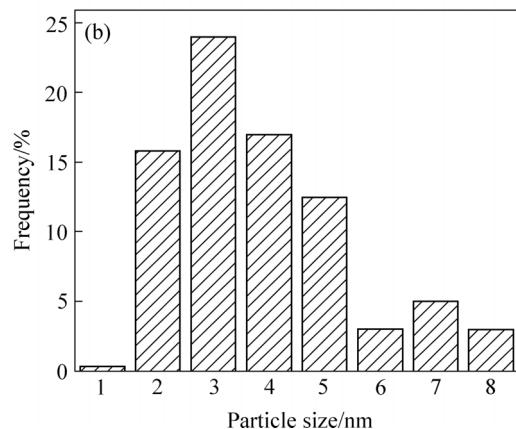

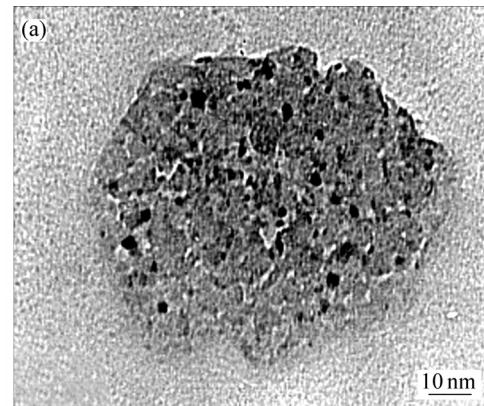

Fig.2 TEM photograph(a) and gold particle size distribution(b) on 2.01Au/Fe-PILC catalyst

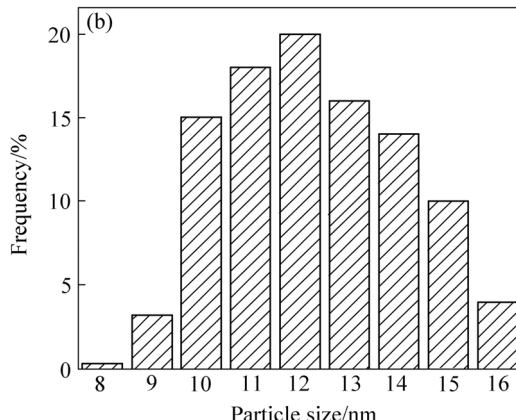

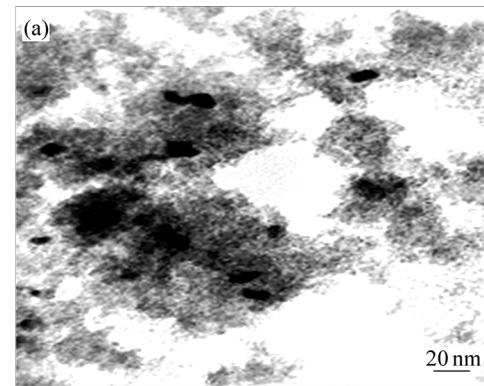

Fig.3 TEM photograph(a) and gold particle size distribution(b) on 2.52Au/Fe-Oxide catalyst

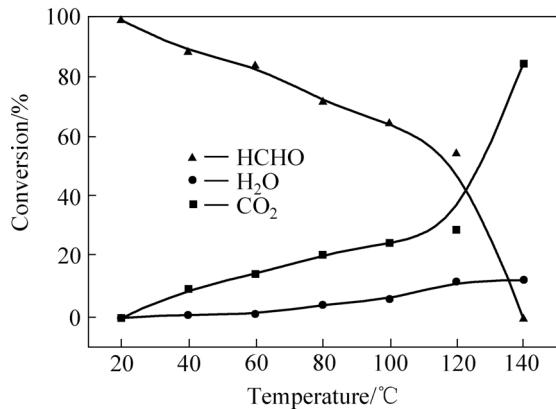

Fig.4 Catalytic combustion of formaldehyde on 2.01Au/Fe-PILLC catalyst

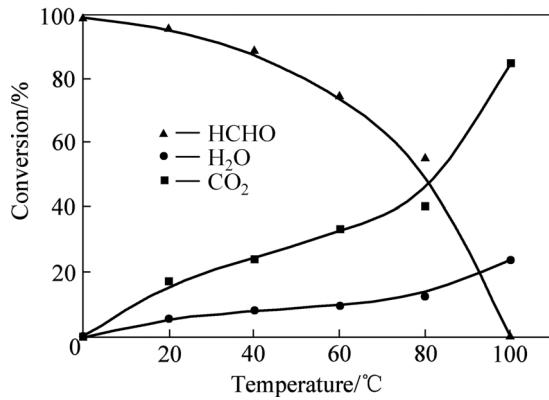

Fig.5 Catalytic combustion of formaldehyde on 2.52Au/Fe-Oxide catalyst

suggested that gold species existing in states with different charges, such as  $\text{Au}^{3+}$ ,  $\text{Au}^{1+}$ ,  $\text{Au}^{\delta+}$  ( $0 < \delta < 1$ ) and  $\text{Au}^0$  on the support are the active components for catalytic combustion of VOCs [9, 15–16].

The XPS spectra of 2.01Au/Fe-PILLC and 2.52Au/Fe-Oxide catalysts in the Au 4f region are illustrated in Fig.6 and Fig.7, respectively. There are two peaks for gold species corresponding to the  $\text{Au} 4f_{7/2}$  and  $\text{Au} 4f_{5/2}$  transitions, but the positions of the peaks vary with the state of the gold species in the samples. In the 2.01Au/Fe-PILLC catalyst, two major peaks in XPS spectra are from different gold species ( $\text{Au}^3$  and  $\text{Au}^0$ ). The peak of  $\text{Au} 4f_{5/2}$  is higher than that of the  $\text{Au} 4f_{7/2}$ , compared with the metallic gold  $\text{Au}^0$  (83.8 and 87.45 eV) [17]. It is highly possible that  $\text{Au(OH)}_3$  coexists with the metallic gold. Moreover,  $\text{Au}^{3+}$  ( $\text{Au} 4f_{7/2}$ , 86.5 eV) species is more than any other gold species[18–20]. It can be seen that metallic gold  $\text{Au}^0$  (83.7.0 and 87.45 eV) and gold species  $\text{Au}^{\delta+}$  (84.9 and 88.6 eV) account for most of the gold species in the 2.52Au/Fe-Oxide catalyst[20–21].

The difference between the binding energies of Au 4f of samples and those of bulk metallic gold can be attributed to partial flow of the 5d electrons of gold into the 3d orbitals of iron or, to some extent, into 6s orbital

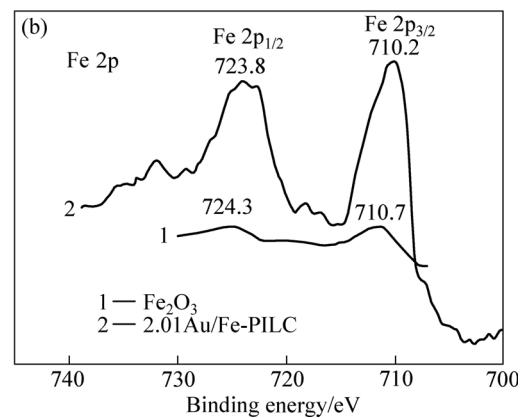

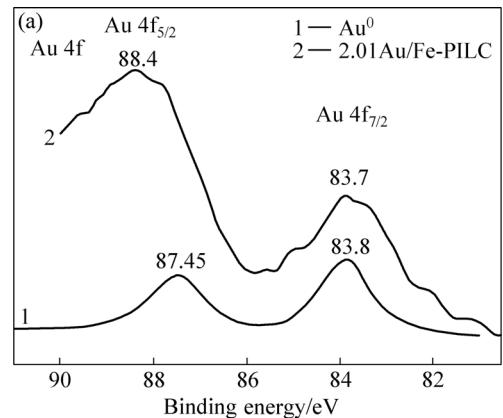

Fig.6 XPS spectra of 2.01Au/Fe-PILC catalyst in Au 4f region(a) and Fe 2p region(b)

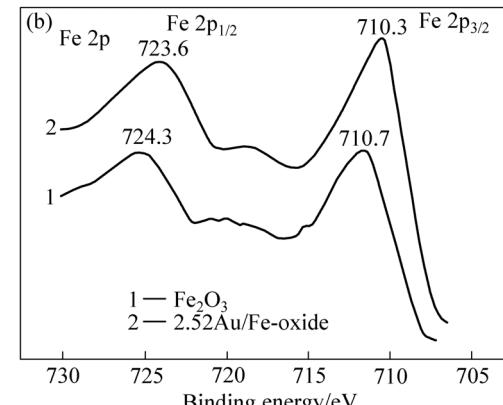

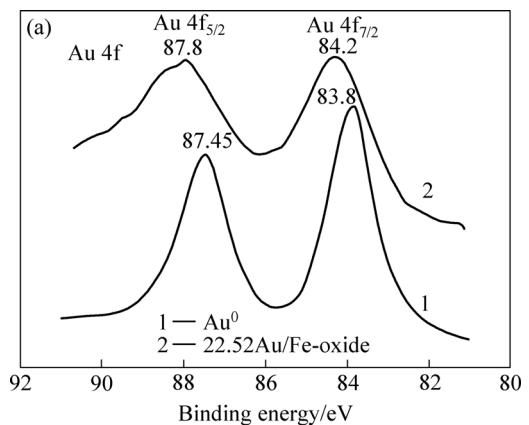

Fig.7 XPS spectra of 2.52Au/Fe-oxide catalyst in Au 4f region(a) and Fe 2p region(b)

of gold itself. Thus, the nuclear attraction in gold atoms is increased, resulting in the increase in the binding energies of Au 4f. The outer orbitals of gold atoms with partial charge have electronic configuration similar to those of Pt element, thus making them active for catalysis. Moreover, the binding energies of Fe 2p decrease slightly and this is attributed to the flow of some electrons into some empty Fe 3d orbitals. The coexistence of different gold species in one catalyst is an interesting phenomenon, which could be attributed to the interaction between the gold clusters and the support.

According to the analysis of activity for catalytic combustion of formaldehyde, active species gold was in state of  $\text{Au}^{3+}$  and  $\text{Au}^0$  coexisting in the 2.01Au/Fe-PILC catalyst, while, active species gold were in state of  $\text{Au}^{\delta+}$  and  $\text{Au}^0$  coexisting in the 2.52Au/Fe-oxide catalyst. By comparing these two catalysts, the higher activity of 2.01Au/Fe-PILC catalyst demonstrates again that small Au nanoparticles coexisting with a certain number of  $\text{Au}^{3+}$  ions are more active for catalytic combustion formaldehyde[14, 22]. It is not difficult to understand that the activity of 2.52Au/Fe-oxide is less than that of 2.01Au/Fe-PILC, even if the content of gold in 2.52Au/Fe-oxide catalyst is more than that of 2.01Au/Fe-PILC catalyst.

## 4 Conclusions

1) The catalytic activity of 2.01Au/Fe-PILC for formaldehyde catalytic combustion is attributed to nano-sized (2–5 nm), highly dispersed gold particles and good adsorption properties of support.

2) Gold species with partial positive charge are active sites, contributing to the catalytic activity. Furthermore, XPS analysis results show that small Au nanoparticles coexisting with a certain number of  $\text{Au}^{3+}$  ions are more active for catalytic combustion formaldehyde than Au nanoparticles coexisting with  $\text{Au}^{\delta+}$ .
