**Abstract:** The microstructure of as-cast  $Zr_{60}Al_{15}Ni_{25}$  bulk metallic glass was investigated by high-resolution transmission electron microscopy. It is found that there exist numerous short-range order regions (SRORs) in the metallic glass though it is identified to be amorphous by X-ray diffraction method. Furthermore, the amorphous degree shows a close correlation with the microstructure of corresponding mother ingot. The crystallization kinetics was investigated by differential scanning calorimetry under isochronal and isothermal conditions. The results show that the crystallization is triggered by the growth of the pre-existing SRORs and the growth is three-dimension diffusion-controlled. The amorphous degree of  $Zr_{60}Al_{15}Ni_{25}$  bulk metallic glass considerably influences its crystallization kinetics, namely, the more homogeneous distribution of atoms results in a more sluggish nucleation behavior. **Key words:**  $Zr_{60}Al_{15}Ni_{25}$  metallic glass; short-range order; crystallization kinetics

### **1** Introduction

A metallic glass is metastable with respect to crystallization as it is heated beyond the glass transition temperature  $(T_g)$ . Zr-based multicomponent bulk metallic glasses have high glass forming ability and exhibit a large supercooled liquid region ( $\Delta T_x$ , defined as the temperature region between  $T_{\rm g}$  and the onset temperature of crystallization  $T_x$ )[1–4]. Their high thermal stability provides a large experimentally accessible time and temperature window to investigate the crystallization kinetics in the supercooled liquid. The influences of other elements on the crystallization of Zr-based amorphous alloys were widely investigated[5-6]. Through the isothermal investigation of the phase transformation within a time scale, a time temperature - transformation (TTT) diagram for a metallic system can be obtained[7]. The knowledge of the progression of the crystallization with time can provide a deeper insight into the crystallization mechanism of a bulk metallic glass.

The atomic configuration of a metallic glass is the resultant of freezing liquid. It has been found that there

exist short-range order regions (SRORs) in metallic glasses by high-resolution transmission electron microscopy (HRTEM) and molecular dynamics simulation[8-9]. Due to the structure heredity, the SRORs in a metallic glass inherit from the corresponding mother liquid alloy, and microstructure of a liquid alloy has heredity from the mother ingot. In this sense, the microstructure of the mother ingot will influence the amorphous degree of the corresponding metallic glass, and its crystallization kinetics. This will lighten the crystallization mechanism of amorphous alloys, which is not well explained within the frame of classical nucleation theory. However, few works have addressed on this aspect.

It has been reported that the  $Zr_{60}Al_{15}Ni_{25}$  metallic glass has a wide  $\Delta T_x$  as high as 77 K[1]. LI et al[10] investigated phase products during the crystallization by analytical transmission electron microscopy (ATEM) and X-ray diffraction (XRD). In the present work, the crystallization kinetics of  $Zr_{60}Al_{15}Ni_{25}$  bulk metallic glass is investigated by differential scanning calorimetry (DSC) under isochronal and isothermal conditions, and the influence of amorphous degree of the metallic glass on its crystallization kinetics is discussed.

### 2 Experimental

Ingots with nominal compositions of Zr<sub>60</sub>Al<sub>15</sub>Ni<sub>25</sub> (mole fraction, %) were prepared by arc melting a mixture of metals Zr, Al and Ni (with purity of better than 99.9 % in mass fraction) in a water-cooled copper crucible under titanium-gettered argon atmosphere. To prevent composition segregation, the original ingots were remelted 4 times at 1 300 K, and were marked with A0. Then, two A0 ingots were repeatedly melted 6 and 12 times at 1 580 K, and the resultant ingots are marked A6 and A12, respectively. The time of each melting operation was 60 s. Under the same preparation conditions, plate specimens with a cross-section of 1 mm×10 mm and length about 50 mm were prepared by suction casting in a copper mold, and their amorphous nature was verified by X-ray diffraction (XRD) using Cu K<sub>a</sub> radiation. For expression convenience, hereafter, the specimens cast from the ingots A0, A6 and A12 were marked with M0, M6 and M12, respectively. The microstructures of ingots were observed by optical The amorphous microstructure was microscopy. observed by HRTEM under an accelerating voltage of 200 kV (JEOL JEM-2100 F). The crystallization processes of metallic glasses were characterized under the conditions of isochronal and isothermal in a differential scanning calorimeter (NETZCH, DSC 404) under flowing high purity argon. In the case of isochronal tests, the DSC plots were recorded at the selected heating rates of 10-40 K/min. For the isothermal analysis, the samples were firstly heated at the rate of 50 K/min to the preset temperature, and then held for a certain period until the completion of crystallization. The Al<sub>2</sub>O<sub>3</sub> and Al pans were utilized for the isochronal and isothermal tests, respectively.

### **3 Results**

The results of chemical analyses indicate that the compositions of ingots do not change after the repeated melting, which excludes the influence of the changes of compositions, especially the content of oxygen, on the crystallization kinetics. Fig.1 shows the microstructures of the ingots A0, A6 and A12. It is clear that the ingot microstructure becomes finer and finer with increasing repeated melting times. Fig.2 shows the XRD patterns of the as-cast specimens M0, M6 and M12, indicating their amorphous nature. The HRTEM images of glasses M0 and M12 are shown in Fig.3, indicating existence of SRORs in the metallic glasses. Based on the statistical mechanism, the calculated Gibbs energy of liquid Zr-Al-Ni system shows that  $Zr_2Ni$  clusters prefer to exist[11]. Therefore, it is reasonably assumed that these

Fig.1 Microstructures of ingots A0 (a), A6 (b) and A12 (c)

Fig.2 XRD patterns of as-cast specimens M0, M6 and M12

SRORs are  $Zr_2Ni$ -like clusters. The average size of SRORs in M12 (about 3 nm) is much smaller than that in M0 (about 7 nm), suggesting that the distribution of

atoms in M12 is more homogeneous than that in M0. Within the frame of classical homogeneous nucleation theory, the critical radius of a nucleus during crystallization of a metallic glass was estimated to be about 1 nm[12]. Then, it is reasonable to consider that the size of SRORs in the  $Zr_{60}Al_{15}Ni_{25}$  bulk metallic glass is overcritical.

**Fig.3** HRTEM images of glasses M0 (a) and M12 (b), showing existence of numerous of short-range order regions

The isochronal DSC plots at the heating rates of 10, 20, 30 and 40 K/min are shown in Fig.4. All the DSC traces show an endothermic event, which is the characteristic of glass transition, followed by a single exothermic event corresponding to the crystallization process. The detailed DSC results of the glasses M0 and M12 are shown in Table 1.

From Table 1, it can be seen that the peak temperature of crystallization  $(T_p)$  increases with increasing heating rate. The effective activation energy for the crystallization  $(E_c)$  can be evaluated by Kissinger equation [13]:

$$\ln \frac{T_{\rm p}^2}{\beta} = \frac{E_{\rm c}}{RT_{\rm p}} + c \tag{1}$$

where  $\beta$  is the heating rate; *R* is the gas constant; *c* is the constant. The Kissinger plots  $\ln(T_p^2/\beta)$  vs.  $1/T_p$  (Fig.5) are approximately straight lines. Based on the slope of these Kissinger plots, the effective activation energies for crystallization (*E*<sub>c</sub>) of glasses M0 and M12 are evaluated to be 345 kJ/mol and 431 kJ/mol, respectively. The

**Fig.4** Isochronal DSC plots of glasses M0 (a) and M12 (b) at different heating rates

 Table 1
 Isochronal DSC data of glasses M0 and M12 at different heating rates

Glass	Heating rate, $\beta/(K \cdot min^{-1})$	Glass transition temperature, $T_g/K$	Exothermic peak temperature, $T_p/K$
M0	10	686.4	763.0
M12	10	697.7	766.6
M0	20	690.5	770.2
M12	20	703.8	771.8
M0	20	694.7	777.2
M12	30	705.3	778.1
M0	40	698.6	781.6
M12	40	708.1	781.9

results indicate that the thermal stability of  $Zr_{60}Al_{15}Ni_{25}$  bulk metallic glass substantially improves due to the repeated melting.

The isothermal DSC traces exhibit a single exothermic peak after a certain incubation period (as exemplified by M0 in Fig.6). The detailed isothermal DSC results of M0 and M12 are shown in Table 2. It can be seen that the incubation time  $\tau$  (defined as the time scale between the time  $t_0$  and  $t_{1\%}$ ,  $t_0$  is the time to reach

Fig.5 Kissinger plots of glasses M0 (a) and M12 (b)

Fig.6 Isothermal DSC plots of glass M0 at different annealing temperatures

the annealing temperature, and  $t_{1\%}$  is the time to reach 1 % crystallized volume fraction) is considerably short at different annealing temperatures, which is attributed to the relatively high annealing temperatures. The value of  $\tau$  increases when the annealing temperature decreases. Meanwhile, the exothermic peak width (referred to the time between 1 % and 95 % of transformation into the crystalline state) increases substantially, indicating a more sluggish crystallization process.

It is assumed that the crystallized volume fraction x, up to any time t, is proportional to the partial area of the exothermic peak. Thus the crystallized volume fraction corresponding to a given time during crystallization can be determined by measuring the partial area of the exothermic peak. The plots of the measured results at different temperatures are shown in Fig.7 (M0 and M12). The curves are typical sigmoid type. The time evolution of the crystallized volume fraction can be modeled by the Johnson-Mehl-Avrami (JMA) equation as follows[14–15]:

$$x(t) = 1 - \exp\{-[k(t-\tau)]^n\}$$
(2)

where x(t) is crystallized volume fraction; t is the annealing time; n (called as Avrami exponent) is a constant related to the behavior of nucleation and growth, and k is a reaction rate constant which depends on temperature T and effective activation energy  $E_c$ :

$$k = k_0 \exp[-E_c / (RT)] \tag{3}$$

where  $k_0$  is a constant, and R is the gas constant.

Based on Eq.(2), an equation can be deduced as

$$\ln[-\ln(1-x)] = n\ln k + n\ln(t-\tau)$$
(4)

By plotting  $\ln[-\ln(1-x)]$  vs.  $\ln(t-\tau)$  at different annealing temperatures using the data x = 15%-85%, the JMA plots can be obtained and shown in Fig.8 (M0 and M12). The plots are nearly straight lines. The Avrami exponent *n* and the reaction rate constant *k* can be calculated from the slope and intercept of the lines and the detailed results are shown in Table 2.

Table 2 Isothermal kinetic	parameters of glasses I	M0 and M12 at different	annealing temperatures
			0 1

Glass	Annealing temperature /K	Incubation time, $\tau/\min$	Avrami exponent, <i>n</i>	Reaction constant, $k/\min^{-1}$	Peak width, $(t_{95\%} - t_{1\%})/min$
M0	743	0.52	1.51	0.24	7.73
M12		0.55	1.42	0.17	10.62
M0	748	0.41	2.32	0.6	2.75
M12		0.45	2.01	0.48	3.47
M0	753	0.39	3.80	0.93	1.42
M12		0.42	2.27	0.86	1.81

M12		0.34	3.62	1.57	0.97

**Fig.7** Crystallized volume fraction as function of annealing time for glasses M0 (a) and M12 (b) at different temperatures

For a glass, the obvious variation of Avrami exponent (Fig.8) indicates a change of mechanism of crystallization at different annealing temperatures. At the same annealing temperature, the Avrami exponent of glass M0 is larger than that of M12, implying a change of the crystallization mechanism.

#### **4** Discussion

## 4.1 Short-range order regions in as-cast metallic glasses

The atomic configuration of an amorphous phase is similar to that of the liquid from which it is frozen. Thus the liquid structure influences the amorphous degree. The microstructure of mother ingot obviously becomes much finer after the repeated melting treatment (Fig.1). Due to the structure heredity, it is assumed that the atomic distribution is more homogeneous in the liquid, from which the amorphous specimens are produced when the ingot with finer microstructure is remelted to the same casting temperature. After the subsequent casting, the average size of the SRORs frozen in the corresponding amorphous phase becomes smaller, which is shown in HRTEM images (Fig.3). These SRORs, so-called

Fig.8 JMA plots for glasses M0 (a) and M12 (b) at different annealing temperatures

quenched-in nuclei, greatly influence the crystallization kinetics.

## 4.2 Crystallization kinetics under isochronal condition

As we know that, after the repeated melting of the mother ingot at 1 580 K, the effective activation energy for crystallization of the corresponding metallic glass obviously increases (Fig.5), which is attributed to the more homogeneous distribution of the atoms in the metallic glass. The results are consistent with our work[16]. The crystallization previous needs redistribution of atoms. The more homogeneous distribution of atoms results in more difficult redistribution of atoms, and therefore, larger effective activation energy (Fig.5).

# 4.3 Crystallization kinetics under isothermal condition

The isothermal crystallization kinetics was investigated at supercooled liquid state (between 743 K and 758 K). The Avrami exponent n provides the characteristics of nucleation and growth during the crystallization. The JMA parameters can be expressed in

terms of the nucleation and growth parameters [17]. The Avrami exponent, n, can be expressed as

$$n = a + bc \tag{5}$$

where *a* is the nucleation index (a = 0 for the nucleation rate of zero; 0 < a < 1 for a decreasing nucleation rate with time; a = 1 for a constant nucleation rate; and a > 1for an increasing nucleation rate), *b* is the dimensionality of the growth (whose value can be 1, 2 or 3) and *c* is the growth index (c = 1 for interface-controlled growth and *c* = 0.5 for diffusion-controlled). The smallest value of *n* is about 1.5 (Table 2). Based on the discussion above, it can be known that the growth is diffusion-controlled during the crystallization, indicating c = 0.5. From Eq.(5), it can be known that the values of *b* for the glasses M0 and M12 at different temperatures can be modeled by 3. Therefore, the growth is three-dimension diffusioncontrolled.

In a multicomponent system, each of the elements has its own diffusion coefficient, and consequently, different elements will generate different concentration gradients. As one of the elements diffuses much more slowly than the rest, its diffusion controls the actual growth rate. When the atom fluxes through the interface are driven by the steady state diffusion, the so-called diffusion-controlled growth is obtained. For the diffusion-controlled growth,  $1 \le n \le 1.5$  indicates the growth of particles with an appreciable initial volume; n= 1.5, the growth of small particles with a nucleation rate close to zero;  $1.5 \le n \le 2.5$ , the growth of small particles with a decreasing nucleation rate; n = 2.5, the growth of small particles with a constant nucleation rate;  $n \ge 2.5$ , the growth of small particles with an increasing nucleation rate[18]. At 743 K, the n values of the glasses M0 and M12 are about 1.5, indicating the growth of pre-existing SRORs with a nucleation rate close to zero. At the temperatures higher 743 K, the n values of the glasses M0 and M12 are larger than 1.5, indicating the growth of pre-existing SRORs accompanied with significant nucleation rates. From Table 2, the *n* values of glass M12 are obviously smaller than those of M0 at the same annealing temperature, which suggests lower nucleation rates of M12 than M0. This further verifies more difficult redistribution of atoms during crystallization of the metallic glass due to the repeated melting treatment; namely, the amorphous degree of a metallic glass considerably influences its crystallization kinetics.

#### **5** Conclusions

1) The repeated melting treatment results in an ingot with finer microstructure, and the atomic distribution in the corresponding  $Zr_{60}Al_{15}Ni_{25}$  metallic glass is more homogeneous.

2) The Avrami exponents indicate that the crystallization of  $Zr_{60}Al_{15}Ni_{25}$  bulk metallic glass starts from the growth of pre-existing overcritical short-range order regions (nuclei), and the growth is three-dimension diffusion-controlled.

3) The amorphous degree greatly influences its crystallization kinetics, namely, the more homogeneous distribution of atoms results in larger effective activation energy for crystallization in the glass M12, and therefore, a more sluggish crystallization behavior.
