Received 18 March 2010; accepted 1 July 2010

**Abstract:** Mechanical alloying and subsequent annealing treatment were carried out to investigate the evolution of the microstructure and morphology of the TiH<sub>2</sub>-Ni system. The Ni(Ti) solid solution was formed in the initial milling process. When the milling time was 60 h, the alloy with uniform elemental distribution showed an amorphous structure containing a small amount of TiH<sub>2</sub> nanocrystalline phase. The annealing treatment at 693 K contributed to a completion of amorphization for the alloy milled for 60 h. For the treatment at 1 073 K, a crystallization reaction for the amorphous phase occurred, leading to the formation of Ti<sub>2</sub>Ni, TiNi, and TiNi<sub>3</sub> compounds by a short time treatment. Moreover, a separation of Ni-rich phases from the matrix and a phase transition among these three compounds occur by a long time treatment.

Key words: Ti-Ni alloy; amorphous alloy; annealing; microstructure

#### **1** Introduction

TiNi alloy is a promising material in the areas of shape memory, corrosion resistance, damping and hydrogen storage[1-4]. Several approaches, such as casting[5], powder metallurgy[6], self-propagating high-temperature synthesis[7] and ion beam deposition[8], have been operated to produce TiNi alloys using elemental powders of Ti and Ni as raw materials. In recent years, a non-equilibrium processing technology, mechanical alloying (MA), has been extensively carried out to synthesize TiNi alloys due to its simplicity, low cost and facility to produce a great amount of materials with metastable phases[9-12]. YE et al[11] reported that amorphous Ti-50%Ni (mole fraction) has was obtained by MA. Similar result has been achieved by GU et al[13]. Ternary Ti-M-Ni disordered alloys (M=Zr, V, Cu, Mn, Fe or B), partially substitution of M for Ti or Ni, could also be prepared by mechanical alloying[4, 14]. MOUSAVI et al[15] found that nanocrystalline TiNi intermetallic could be synthesized by MA without subsequent heat treatment. The studies on crystallization behaviors of TiNi alloys containing metastable phases indicated that three

compounds, namely TiNi,  $Ti_2Ni$ , and  $TiNi_3$ , could be formed by annealing treatment[11, 13, 15].

In this work, we synthesized a TiH<sub>2</sub>-Ni alloy by using raw materials of TiH<sub>2</sub> and Ni powders. The effects of mechanical alloying (MA) and subsequent annealing treatment on the microstructure and morphology of the TiH<sub>2</sub>-Ni powders were investigated. The crystallization behavior of the milled powders was also studied.

#### **2** Experimental

#### 2.1 Sample preparation

Powders of TiH<sub>2</sub> (50  $\mu$ m, 99.9%) and Ni (35  $\mu$ m, 99.9%) were blended together to form a nominal composition of TiH<sub>2</sub>-50%Ni (mole fraction). They were loaded into a stainless-steel container with stainless-steel balls (10 mm and 20 mm in diameter) under an argon atmosphere. The ball to powder ratio was 20:1. The milling was performed in a planetary mill with a rotation speed of 300 r/min and the milling time was 20, 40 or 60 h. The three milling periods were all carried out continuously without interim sampling. The powders milled for 60 h were subsequently annealed at 693 K for 0.5 h, at 1 073 K for 1 h or at 1 073 K for 8 h under an

argon atmosphere.

#### 2.2 Characterizations

X-ray diffraction (XRD) with Cu  $K_{\alpha}$  radiation was carried out in a Thermo ARL X' TRA diffractometer system to determine the structures of the milled and annealed powders. Transmission electron microscopy (TEM) was also employed for structure observation on the sample after annealing treatment on a JEM 2000 EX unit. Differential thermal analysis (DTA) and thermogravimetry (TG) at a heating rate of 0.33 K/s was performed to present the structural and phase transition treatment. during annealing Scanning electron microscopy (SEM) was used to analyze the morphologies of the samples by a JSM-5900 unit.

### **3 Results and discussion**

#### 3.1 Mechanical alloying

Fig.1 shows the variation of XRD patterns for the TiH<sub>2</sub>-Ni powders as a function of milling time or heat treatment. It is apparent that the intensities of the diffraction peaks corresponding to the raw materials TiH<sub>2</sub> (Cubic, PDF card No. 65—708) and Ni (Cubic, PDF card No. 65—2865) are obviously decreased after 20 h of milling. In addition to decreasing the intensity, continuous ball milling induced considerable broadening of the peaks. This is due to the grain size refinement and the increase in the internal strain induced by MA. The formation of an amorphous phase can be inferred by the peak shape and the background of the pattern for the milled powders at  $2\theta$  between  $37^{\circ}$  and  $47^{\circ}$ .

**Fig.1** XRD patterns of milled and subsequently annealed TiH<sub>2</sub>-Ni powders

A gas flowmeter was used to detect the pressure within the milling container at the end of each milling period. It was found that the pressure was almost unchanged after 20 h of milling as compared with the non-milled one, while a drastic increase and a slight increase of the pressure occurred when the milling periods were 40 and 60 h, respectively. This means that hydrogen gas was formed within the container after 40 h of milling. Moreover, the open potentials of the electrodes prepared by the milled powders are -0.989, -0.878 and -0.941 V (vs. Hg/HgO) when the milling periods are 20, 40 and 60 h, respectively. Accordingly, three stages of the milling process can be obtained. The first is the short milling period (in 20 h). In this time range, mechanical milling (MM) leads to a decrease of the stability of titanium hydride and consequently a number of hydrogen atoms adsorb on the powder surface, resulting in the occurrence of hydrogen desorption or hydrogen evolution reaction in the 6 mol/L KOH electrolyte, and thus a large negative open potential of the powders milled for 20 h is presented. In the next time range (from 20 to 40 h), the energy induced by the milling contributes to not only an alloying process (Fig.1), but also the formation of hydrogen gas caused by the decomposition of TiH<sub>2</sub> during milling, and thus, the hydrogen concentration on the powder surface is reduced, resulting in the increases of the open potential of the milled powders and the pressure within the container. For further milling (from 40 to 60 h), part of the hydrogen gas is dissociated and subsequently absorbed by the powders, leading to the decreases of the potential of the powders and the pressure. It is interesting that there is no occurrence of hydrogen evolution reaction when the electrode containing the powders milled for 60 h was immersed in the KOH solution, which means that the powders milled for 60 h are more stable. The long time MA induces the alloying between titanium hydride and nickel.

Fig.2 shows that the displacement of Ni peak for the milled powders towards lower angles with increasing the milling time. This indicates that the lattice parameter of

Fig.2 Displacement of Ni peak to lower angles for samples milled at 693 K for different time

Ni increased as the milling time increased due to the diffusion of Ti atoms, formed by the decomposition of TiH<sub>2</sub>, into the lattice of Ni, resulting in the formation of a Ni(Ti) solid solution. Similar results have been found in the Ti-Ni system of Refs.[13, 15]. No intermetallic phase was formed in TiH<sub>2</sub>-Ni system during MA. When the milling time was 60 h, the milled product is now predominantly amorphous with a small amount of TiH<sub>2</sub> nanocrystalline phase.

#### **3.2 Annealing treatment**

Fig.3 shows the DTA and TG curves of the TiH<sub>2</sub>-Ni powders milled for 60 h. Two exothermic peaks were observed in the applied temperature region. NEVES et al[16] have proposed that in the MA process a great amount of defects were introduced into such as vacancy, dislocation and lattice strain. Therefore, structure relaxation should occur during the DTA test, leading to an exothermic reaction.

Fig.3 DTA and TG curves of TiH2-Ni powders milled for 60 h

An annealing treatment for the milled powders at 693 K for 0.5 h was carried out. It is interesting that the treated powders showed an amorphous structure characterized by XRD, as shown in Fig.1. This was confirmed by the result of TEM, as shown in Fig.4. The annealing resulted in the disappearance of the diffraction peak of TiH<sub>2</sub> of the powders milled for 60 h, as shown in Fig.1. Fig.3 demonstrates that the mass of the powders decreased during the annealing in temperature region below 700 K. A subsequent increase of the mass may be attributed to an oxidation process. The mass loss may be ascribed to two causations, namely the decomposition of TiH<sub>2</sub> and hydrogen desorption of the amorphous matrix. SUH et al[17] reported that hydrogen atoms could induce a transformation from nanocrystalline phase to amorphous phase. Similar hydrogen-induced amorphization has been mentioned earlier[18]. It is possibly that the decomposition of TiH<sub>2</sub> and hydrogen diffusion in the alloy matrix destroy the long-range order

structure during the annealing process, and thus lead to a rearrangement of metallic atoms into short-range order, resulting in the formation of amorphous phase. Moreover, the composition of the amorphous phase of the treated alloy is different from that of the alloy milled for 60 h according to the shift of diffraction peaks to lower angle, as shown in Fig.2. The annealing treatment at a high temperature, based on the second exothermic peak shown in Fig.3, contributes to the formation of Ti-Ni intermetallic compounds: Ti2Ni, TiNi and TiNi3, as shown in Fig.1. The alloy treated for 1 h has a predominant composition of Ti<sub>2</sub>Ni coexisting with minor phases of TiNi and TiNi<sub>3</sub>, while the alloy treated for a long time mainly consists of TiNi phase and shows an increase in TiNi<sub>3</sub> phase but a drastic decrease in Ti<sub>2</sub>Ni phase. Perhaps, this is attributed to a higher stability for the short-range order structure corresponding to Ti-50%Ni (mole fraction), which requires a long time for a completion of crystallization.

**Fig.4** TEM image of  $TiH_2$ -Ni powder milled for 60 h and subsequently annealed at 693 K for 0.5 h

Fig.5 shows the backscattered electron (BSE) images of the milled and subsequently annealed TiH<sub>2</sub>-Ni powders. It is well-known that cold-welding and fracture are the two essential processes involved in the milling process[19]. TiH<sub>2</sub> and Ni particles were cold welded together by the energy introduced by MA, leading to the formation of a lamellar structure, as shown in Fig.5(a). It can be seen from Fig.5(b) that this lamellar structure disappeared and the elemental distribution in the particle was uniform when the powders were milled for 60 h. The result of XRD demonstrates that the annealing treatment promoted the internal diffusion and a short-range rearrangement of the milled powders at a low temperature, resulting in a completion of amorphization.

It might be that this rearrangement favors the atoms of Ti and Ni to form small clusters; these distributed clusters act as nucleation sites, and the nucleation grows up when a high temperature is applied. Fig.5(c) and Fig.5(d) show that no evident phase separation occurred by the annealing treatment at a low temperature or at a high temperature for a short time. However, the result of XRD shown in Fig.1 demonstrates that the alloy treated at 1 073 K for 1 h contains three phases. Therefore, it is probably that three phases are uniformly distributed and thus the corresponding BSE image presents no evident contrast. When the milled powders were annealed at a high temperature for a long time, Ni-rich phases were evidently separated from the matrix, as shown in Fig.5(e). Apparently, the white region is mainly composed of TiNi<sub>3</sub> according to the result of XRD shown in Fig.1. The long time annealing treatment induces a phase transition among the Ti-Ni intermetallic compounds.

## **4** Conclusions

1) Mechanical milling induced a cold welding between  $TiH_2$  and Ni powders, leading to the formation of a lamellar structure in the initial milling process. The

Ni(Ti) solid solution was formed during the milling process.

2) The elemental distribution of the milled powders tended to be uniform when a long time milling was applied. The powders milled for 60 h had an amorphous structure containing a few nanocrystalline  $TiH_2$  phases.

3) The annealing treatment at 693 K resulted in a completion of amorphization for the powder milled for 60 h. The treatment at a high temperature of 1 073 K contributed to a crystallization of the amorphous phase and, accordingly, the formation of  $Ti_2Ni$ , TiNi and  $TiNi_3$ . A long time treatment at 1 073 K induced the occurrence of phase separation and phase transition among these three compounds.
