Received 8 April 2011; accepted 16 June 2011

**Abstract:** First-principle calculation was used to investigate the magnetic properties, electronic structure and bonding mechanism of FeF<sub>2</sub>. By calculating the lattice parameters and magnetic moment as a function of effective interaction parameter ( $U_{eff}$ ), it is found that the optimum value of  $U_{eff}$  is equal to 4 eV, the magnetic moment is 3.752 µB and the value of c/a is 0.704, which are in good agreement with the experiment results. Simultaneously, on the basis of GGA+U method, the electronic structure and bonding mechanism of FeF<sub>2</sub> were investigated by the analysis of electron localization function, Bader charge and total charge density. The results show that the bonding behavior between Fe and F atoms is a combination of ionic and covalent bond. **Key words:** magnetic moment; electronic structure; bonding mechanism; FeF<sub>2</sub>; lithium-ion battery

#### **1** Introduction

Lithium-ion batteries as power source have been widely used in various energy storage fields due to high energy density and good cycling stability [1, 2]. The commonly used cathode materials for lithium-ion batteries are the layered intercalation compounds, such as LiCoO<sub>2</sub>, LiMnO<sub>2</sub>, LiFePO<sub>4</sub>.

Recently, metal fluorides are considered next generation lithium ion battery cathode materials and enter a prominent space in energy storage [3-5]. The reaction between Li and metal fluorides can be expressed by the following equation:

$$xLi^+ + xe + MeF_x \leftrightarrow xLiF + Me$$
 (1)

where Me is metal, such as Fe, Co, Ni, Bi; e is the charge of an electron. Due to the high ion bonding character between metal and high electro-negativity of F ions and full use of their valence electrons in charge/discharge process, the chemical energy can be reversibly utilized in metal fluorides through conversion reaction (1), which results in high average voltage and high specific capacity. For example, the theoretical average voltages of  $CrF_3$  and  $FeF_2$  are 2.28 and 2.66 V, respectively [6, 7].

Among all metal fluorides, FeF<sub>2</sub> with theoretical voltage of 2.66 V is considered a promising cathode material for the application of lithium ion battery owing to its low cost and low toxicity. In order to analyze the intrinsic electronic structure of FeF2, theoretical calculations on FeF2 have also been carried out. BROWN et al [8] found that the Fe-F interactions presented some covalent bond characters by means of  $DV-X_{\alpha}$  method. The magnetic coupling constants between nearest-neighbor magnetic ions in FeF2 were calculated using Hartree-Fock method [9]. PHILIPP et al [10] calculated the energy gap and spin-magnetic moments for FeF<sub>2</sub> by using the generalized gradient approximation (GGA) and local-spin-density approximation (LSDA) methods. The result shows that LSDA calculation fails (making them metallic) and GGA calculation yields improvement on the energy gap over LSDA calculation, but the energy gap is very small (0.4 eV), which cannot describe the wide band gap character state of FeF<sub>2</sub>. Besides, the spin-magnetic moment calculated by GGA calculations  $(3.5 \mu B)$  is

lower than the experimental result ( $3.75 \mu B$ ).

Based on the above discussions, because on-site coulomb interaction exists between Fe 3d and GGA method is not enough to well describe the wide band gap character of the compound, the introduction of a Hubbard-like contribution on the Fe 3d states is necessary. Hence, GGA+U method is put forward. U is the Hubbard parameter, which reflects the strength of the on-site coulomb interaction. Up to date, no attempt was carried out on using GGA+U method to study the structure of FeF<sub>2</sub>. In this work, first-principle calculation within GGA+U method was used to investigate the magnetic and electronic properties as well as bonding mechanism of FeF<sub>2</sub>.

#### 2 Computational method

The calculations were performed using the ab-initio total-energy and molecular-dynamics program Vienna ab-initio simulation program (VASP) developed at the institut für Materialphysik of the Universität Wien [11–14]. The projector augmented wave (PAW) method was implemented in VASP. The approximation used for exchange and correlation energies is GGA. For GGA calculations, the Perdew-Burke-Ernzonhof (PBE) exchange-correlation functional was chosen. To study the strong correlation character of 3d electrons of Fe, GGA+U method was employed. Within the GGA+Uapproach, the on-site coulomb term U and the exchange term J were considered together. Effective interaction parameter  $(U_{\text{eff}})$  can be concluded by U-J. In order to obtain the appreciate value of U, the electronic structure of  $FeF_2$  was investigated with the U parameters changing from 1 to 10 eV. The U value was determined through the comparison of equilibrium cell parameters with the available experimental data. The J value was fixed as 1 eV. The cutoff energy of 520 eV and Monkhorst-Pack grid  $(6 \times 6 \times 9)$  for k point sampling in the first irreducible Brillouin zone were used to ensure the good convergence for total energy and forces acting on the atoms. All atoms were fully relaxed until the Hellman-Feynman forces on the atoms were converged to less than  $1 \times 10^{-3}$  eV/nm by a Quasi Newton (QN) algorithm method.

To obtain the electronic density of states (DOS), the tetrahedron method with Blöchl corrections was used for the Brillouin-zone integration and a  $8 \times 8 \times 12$  Monkhorst-Pack *k*-point mesh was set. In all calculations, spin-polarized calculations were performed.

#### **3 Results and discussion**

#### 3.1 Crystal structure of FeF<sub>2</sub>

FeF<sub>2</sub> has a tetragonal structure (with two formula units per unit cell) with space group  $P4_2$ /mnm. Usually, it

can be described by 3 structural parameters: a, c and internal parameter u. a and c are 0.46945 and 0.33097 nm, respectively. The positions of the atoms inside the unit cell are (0, 0, 0) and (1/2, 1/2, 1/2) for the Fe atoms, and (u, u, 0), (1-u, 1-u, 0), (1/2+u, 1/2-u, 1/2) and (1/2-u, 1/2+u, 1/2) for the F atoms, where u is 0.301 [15]. After the structure of FeF<sub>2</sub> is fully relaxed, u is 0.299.

## 3.2 Ferromagnetic and antiferromagnetic phase of FeF<sub>2</sub>

The dependence of the total energies on  $U_{\rm eff}$  for ferromagnetic (FM) and antiferromagnetic (AFM) phase is calculated and shown in Fig. 1. As seen from Fig. 1, with the increase of U values, the energy difference between AFM and FM phases decreases; the energy difference between AFM and FM phases is negligible when  $U_{\rm eff}$  value is higher than 3.0 eV. Generally speaking, the total energy of AFM phase is lower than that of FM phase, which indicates that AFM phase is more stable than FM phase. Hence, in the following calculations, only the AFM phase is considered in investigating the magnetic and electronic properties of FeF<sub>2</sub>.

**Fig. 1** Energy difference between AFM phase and FM phase  $(E_{AFM}-E_{FM})$  within GGA+U as function of  $U_{eff}$ 

#### 3.3 Geometry and magnetic properties

The calculated lattice constant *a* and experimental value are compared in Fig. 2. As seen from Fig. 2, it is clear that the GGA+U method overestimates the lattice constant, and the error increases with the increase of  $U_{\text{eff}}$  value. Even though the theoretical error is below 1.5% compared with experimental value, the calculated lattice constant is still in reasonable agreement with the experiment. Figure 3 shows the tendency of c/a value as a function of  $U_{\text{eff}}$ . It can be found that the value of c/a decreases with the increase of  $U_{\text{eff}}$  value, and it is the closest to the experimental value at  $U_{\text{eff}} = 4$  eV. Moreover, a series of  $U_{\text{eff}}$  values are employed to calculate the magnetic moment of Fe<sup>2+</sup> in FeF<sub>2</sub>. The

Fig. 2 Errors between calculated lattice constant and experimental value

**Fig. 3** Ratio of *c* and *a* parameters (c/a) within GGA+*U* as function of  $U_{\text{eff}}$ 

calculated results are shown in Fig. 4. It is observed from Fig. 4 that the magnetic moment of  $Fe^{2+}$  increases with the increase of  $U_{\text{eff}}$ , and it is 3.752 µB at  $U_{\text{eff}}$ =4 eV, which is in good agreement with the reported experimental value of 3.750 µB [16]. In order to further understand the magnetic properties of FeF2, the calculated spin density is plotted for the FeF2 (110) plane using GGA+U ( $U_{eff}$ =4 eV) method, as shown in Fig. 5. According to spin-up and spin-down electrons, Fe atoms are classified as Fe1 and Fe2, and F atoms are classified as F<sub>1</sub> and F<sub>2</sub>, respectively. As seen from Fig. 5, it is obvious that the magnetic properties of FeF<sub>2</sub> are mainly contributed from the magnetic moment of Fe atoms. As for F atoms, they exhibit very small induced spin magnetic moment by Fe atoms. The calculated spin magnetic moments of Fe and F atoms of  $FeF_2$  are listed in Table 1. Apparently, the spin magnetic moment of Fe is chiefly contributed by Fe 3d state. Moreover, it is interesting that a small spin polarization on the site of F atoms appears, indicating that Fe1-Fe2 superexchange interaction occurs in virtue of F atoms.

**Fig. 4** Magnetic moment within GGA+U as function of  $U_{eff}$ 

**Fig. 5** Spin density of FeF<sub>2</sub> AFM phase in  $(1\overline{10})$  plane in GGA+ $U(U_{eff}=4)$ 

**Table 1** Atomic orbit magnetic moments in FeF<sub>2</sub> crystal cell within GGA+ $U(U_{eff}=4 \text{ eV})$ 

Atom	<i>m</i> (s)/µB	<i>m</i> (p)/µB	$m(d)/\mu B$	Total/µB
Fo	0.022	0.012	2 717	3.752
геı	0.022	0.015	5./1/	3.75 [16]
Fe <sub>2</sub>	-0.021	-0.014	-3.720	-3.755
$\mathbf{F}_1$	-0.002	0.000	0.000	-0.002
$F_2$	0.001	0.004	0.000	0.005

#### 3.4 Electronic structure of FeF<sub>2</sub>

The calculated total DOS together with the partial density of states (PDOS) of FeF<sub>2</sub> using the GGA and GGA+ $U(U_{eff}$  =4) methods are compared in Fig.6. It can be seen that the band gap calculated by GGA method is close to 0. The inclusion of correlation effect  $U_{eff}$ =4.0 eV for FeF<sub>2</sub> can push the states at Fermi level away from Fermi level and reproduce the wide band gap character of the compound. The GGA+U calculations show that FeF<sub>2</sub> belongs to Mott-Hubbard materials with a band gap of 2.565 eV. Therefore, the GGA+U calculations can better predict the electronic structure of FeF<sub>2</sub> than GGA calculation. Further analysis on the DOS of FeF<sub>2</sub> is

carried out. The valence band is divided into two regions. One is located between -7.34 and -1.05 eV, which shows significant hybridization of Fe3d and F2p. The other is located between -1.05 eV and Fermi level, which is composed of mainly Fe3d and small F2p. Besides, the conduction band is located between 2.57 and 8.28 eV.

**Fig. 6** Total and partial DOS for FeF<sub>2</sub> AFM phase within GGA (a) and GGA+U (b) ( $U_{eff}$ =4 eV) (Fermi level was set 0, positive and negative DOS represents spin up and down DOS, respectively.)

In order to analyze the bonding mechanism of  $FeF_2$ , the charge density distribution of  $FeF_2$  is plotted in Fig. 7. It is found that the charge density around Fe and F ions is spherical distributed with slightly directional character toward the direction to their nearest neighboring atoms, indicating that a little covalent bond exists between Fe and F atoms.

The bonding mechanism can be also further analyzed by electron localization function (ELF) [17, 18]. The value of ELF ranges from 0 to 1.0 with ELF=0.5 corresponding to the free electron gas distribution. An ELF value equal to 1.0 means perfect electron localization. The calculated ELF maps in the (1 $\overline{10}$ ) plane of FeF<sub>2</sub> are given in Fig.8. The ELF values of

interstitial region between Fe and F atoms are small but none zero, which indicates the bonding between Fe and F atoms processes ionic nature. Hence, the bonding behavior between Fe and F atoms is the combination of covalent bonding and ionic interactions.

**Fig. 7** Calculated total charge density of FeF<sub>2</sub> AFM phase in  $(1\overline{10})$  plane within GGA+*U* at  $U_{\text{eff}}$  =4 eV

**Fig. 8** Calculated plots of ELF of FeF<sub>2</sub> AFM phase within GGA+U at  $U_{eff}=4 \text{ eV}$ 

To describe the covalent and ionic nature quantitatively, the net charges on Fe and F ions are calculated using Bader's AIM theory [19, 20]. The results are listed in Table 2. As seen from Table 2, it is evident that about 1.5503 electrons transfer from each Fe atom to F atoms. However, net charge on Fe and F atoms are less than nominal charges of the ions (+2 for Fe and -1 for F). Accordingly, in FeF<sub>2</sub>, the bond between Fe and F atom shows evident ionic character and a little covalent bond exists between Fe and F atoms at the same time.

**Table 2** Net charge on atoms of Fe and F in  $FeF_2$  calculated using Bader charge analysis

<u></u>					
Charge	Fe	$F_1$	$F_2$		
Net	1.5503	-0.7754	-0.7749		
Nominal	+2	-1	-1		

#### **4** Conclusions

1) FeF<sub>2</sub> AFM phase is more stable than FeF<sub>2</sub> FM phase considering the strongly correlated Fe 3d, which is consistent with the experimental results. It is well known that GGA calculations result in a metallic state, while GGA+U method can well describe the wide band gap character of FeF<sub>2</sub> and the calculated band gap is 2.565 eV.

2) The optimum value of  $U_{\text{eff}}$  is equal to 4 eV, the magnetic moment is 3.752 µB, and the value of c/a is 0.704, which is in good agreement with the experimental results.

3) It can be concluded that the bond between Fe and F atoms in  $\text{FeF}_2$  is a mixture of ionic bond and covalent bond.
