Received 23 September 2011; accepted 5 January 2012

Abstract: Departing from an analytical phase transformation model, a new analytical approach to deduce transformed fraction for non-isothermal phase transformation was developed. In the new approach, the effect of the initial transformation temperature and the accurate "temperature integral" approximations are incorporated to obtain an extended analytical model. Numerical approach demonstrated that the extended analytical model prediction for transformed fraction and transformation rate is in good agreement with the exact numerical calculation. The new model can describe more precisely the kinetic behavior than the original analytical model, especially for transformation with relatively high initial transformation temperature. The kinetic parameters obtained from the new model are more accurate and reasonable than those from the original analytical model.

Key words: non-isothermal transformation; analytical model; initial transformation temperature; approximation

1 Introduction

In studies of solid-state phase transformations involving nucleation and growth, the classical Johnson-Mehl-Avrami (JMA) approach [1,2] or modified JMA approach [3,4] always plays a central role. The JMA equation can only be validated under certain condition, in particular for nucleation. Under these conditions, the kinetic parameters should be constant during the course of the transformation. Recently, a more general modular, analytical phase transformation model [5,6], has been proposed which recognizes the three mechanisms, nucleation, growth, and impingement of growing new phase particles, as entities that can be modeled separately. The model leads to equations for the degree of transformation which have the structure of JMA equation but with variable kinetic parameters. The analytical model has been successfully used for description of the crystallization of some amorphous alloys [7,8].

Actually, an assumption, $T >> T_0$ (T and T_0 represent the transformation temperature and the initial transformation temperature, respectively) is made in deducing the analytical model [5] for non-isothermal transformation, so, in the temperature range considered, the values of the terms involving T_0 can be neglected in comparison with the corresponding terms involving T. Neglecting terms involving T_0 can also be found in many commonly used methods of non-isothermal kinetics analysis [9,10]. During the last decade, some scientists [11,12] realized that in a limited number of cases including low temperature reactions and multi-stage reactions [13] (T_0 for the consecutive second or third, etc. transformation is relative high), the effect due to T_0 terms cannot be neglected in the kinetic analysis. Furthermore, in deducing the analytical model for non-isothermal transformation, the so-called "temperature integral" [12] or "general temperature integral" [14] cannot be solved analytically and has to be approximated. The approximation applied to analytical model is too coarse to give a sufficiently precise description for non-isothermal transformation.

As the reasons mentioned above, the original analytical model cannot be used widely. In this work, the analytical model is extended to a more general case by using a new analytical approach. The precision of the new model is also evaluated by the numerical calculation. Because it incorporates the effect of T_0 and the accurate "temperature integral" approximation, the new model

can be applied to describing precisely the kinetic behavior of the transformation with high initial transformation temperature.

2 Theoretical background

2.1 Modes of nucleation

The term "site saturation" is used here for the case of initial nucleation site saturation where all nuclei are present at T_0 already. This implies for the nucleation rate at time τ [8]:

$$\dot{N}(T(\tau)) = N^* \delta \left(\frac{T(\tau) - T_0}{\Phi} \right)$$
(1)

with δ denotes Dirac functions; N^* is the number of nuclei per unit volume; $\Phi(=dT/d\tau=dT/dt)$ is the constant heating rate with $T(\tau)=T_0+\Phi\tau$.

The "continuous nucleation" rate per unit volume (i.e. the rate of formation of particles or nuclei of supercritical size) is at a large undercooling only determined by the rate of the jumping of atoms through the interface between the nucleus of critical size and the parent phase, which can be given by an Arrhenius term:

$$\dot{N}(T(\tau)) = N_0 \exp\left(-\frac{Q_{\rm N}}{RT(\tau)}\right) \tag{2}$$

where N_0 is a temperature-independent pre-exponential factor, and Q_N is the temperature-independent activation energy for nucleation.

Here, a short introduction is given for (more general) mixed nucleation in non-isothermal transformation. "Mixed nucleation" represents a combination of site saturation and continuous nucleation modes: the nucleation rate is equal to some weighed sum of the nucleation rates according to continuous nucleation and site saturation [8]. Hence,

$$\dot{N}(T(\tau)) = N^* \delta\left(\frac{T(\tau) - T_0}{\Phi}\right) + N_0 \exp\left(-\frac{Q_N}{RT(\tau)}\right)$$
(3)

where N^* and N_0 include the relative contributions of the two modes of nucleation.

2.2 Modes of growth

The "diffusion-controlled" and the "interfacecontrolled" growth modes can be given in a compact form. At time *t* (i.e. temperature $T(t)=T_0+\Phi(t)$) the volume *Y* of a particle nucleated at time τ (i.e. temperature $T(\tau)$) is given by [8]:

$$Y(T(t)) = g \left[\int_{T(\tau)}^{T(t)} \nu \mathrm{d} \frac{T}{\Phi} \right]^{d/m}$$
(4)

where g is a particle-geometry factor; v is the growth

velocity; *m* is the growth mode parameter (m=1 for interface-controlled growth; m=2 for volume diffusion-controlled growth); *d* is the dimensionality of the growth (d=1, 2, 3) [8].

For a large undercooling, $v=v_0\exp\{-Q_G/[RT(t)]\}$ with Q_G as the temperature-independent activation energy for growth. For interface-controlled growth, v_0 is a temperature-independent pre-exponential factor and Q_G represents the energy barrier at the interface. For volume diffusion-controlled growth, v_0 equals the preexponential factor for diffusion D_0 and Q_G represents the activation energy for diffusion Q_D [8].

2.3 Impingement

The number of supercritical nuclei formed in a unit volume at time τ during a time lapse, $dT(\tau)/\Phi$, is calculated by Eqs. (1)–(3) for different modes. The volume of each of these nuclei grows from τ (i.e. $T(\tau)$) to t (i.e. T(t)) according to Eq. (4) where it is supposed that every particle grows into an infinitely large parent phase, in the absence of other growing nuclei. In this hypothetical case, the volume of all particles at temperature T, called the extended transformed volume, V^{ϵ} , can be described as:

$$V^{e} = \int_{T_{0}}^{T} V \dot{N}(T(\tau)) Y(T) \mathrm{d} \frac{T(\tau)}{\Phi}$$
(5)

with *V* as the sample volume, which is supposed to be constant throughout the transformation. Accordingly, the extended transformed fraction, x_e , is defined as $x_e = V^e/V$.

In reality, the particles do not grow individually into an infinitely large parent phase. A relationship between the real transformed fraction, f, and the extended transformed fraction, x_{e} , is required. Several equations for different types of hard impingement were summarized in Ref. [8]. In this study only the mode of random dispersed nuclei is taken into consideration [2]:

$$\frac{\mathrm{d}f}{\mathrm{d}x_{\mathrm{e}}} = 1 - f \quad \text{and} \quad f = 1 - \exp(-x_{\mathrm{e}}) \tag{6}$$

3 New analytical approach

Upon deriving the original model, the terms involving T_0 are assumed as negligible, and the "temperature integral" and the "general temperature integral" are doing a coarse approximation. In this section, an analytical approach incorporating the effect of T_0 , the more accurate and recently proposed "temperature integral" approximation will be shown.

Assuming mixed nucleation, interface-controlled growth, the extended volume can be given as (see Eqs. (3), (4) and (5)):

JIANG Yi-hui, et al/Trans. Nonferrous Met. Soc. China 22(2012) 1176-1181

$$V^{e} = V \int_{T_{0}}^{T} \left(N^{*} \delta \left(\frac{T(\tau) - T_{0}}{\Phi} \right) + N_{0} \exp \left(-\frac{Q_{N}}{RT(\tau)} \right) \right)$$
$$g \left(\int_{T(\tau)}^{T} v_{0} \exp \left(-\frac{Q_{G}}{RT(t)} \right) d \frac{T(t)}{\Phi} \right)^{d/m} d \frac{T(\tau)}{\Phi}$$
(7)

To avoid unnecessary, nonessential complications in the following formulas, set d/m=1 (the analytical process for other value of d/m is similar). Hence, Eq. (7) can be rewritten as:

$$V^{e} = Vgv_{0} \int_{T_{0}}^{T} \left(N^{*} \delta \left(\frac{T(\tau) - T_{0}}{\Phi} \right) + N_{0} \exp \left(-\frac{Q_{N}}{RT(\tau)} \right) \right) \cdot \int_{T(\tau)}^{T} \exp \left(-\frac{Q_{G}}{RT(t)} \right) d \frac{T(t)}{\Phi} d \frac{T(\tau)}{\Phi}$$
(8)

To derive the analytical expression of Eq. (8), the so-called "temperature integral" and/or "general temperature integral" must be approximated. Recently, it has been found that the approximations in the analytical model could be replaced by the high accuracy approximations [15]. The high accuracy approximations, which guarantee the accuracy of the analytical description, for the "general temperature integral", can be expressed as [14]:

$$\int_{0}^{T} T(t)^{M} \exp\left(-\frac{Q'}{RT(t)}\right) dT(t) = \frac{RT^{M+2} \exp\left(-\frac{Q'}{RT}\right)}{Q'} p_{M}(x)$$
(9)

where x=Q'/(RT) (e.g. $x_G=Q_G/(RT)$, $x_{N,iG}=(Q_N+iQ_G)/(RT)$, i=0, 1, 2, 3...); Q' is the constant activation energy; M is a constant; $p_M(x)$ represents the function of M and x. For M=0, the left-hand side of Eq. (9) becomes the "temperature integral" [12]. It can be expressed as:

$$\int_0^T \exp\left(-\frac{Q'}{RT(t)}\right) dT(t) = \frac{RT^2 \exp\left(-\frac{Q'}{RT}\right)}{Q'}q(x)$$
(10)

where q(x) represents the function of x. The formulas for $p_M(x)$ and q(x) are different according to the different approximate methods [15]. Applying the approximation for "temperature integral" and "general temperature integral", Eq. (8) becomes,

$$V^{e} = Vgv_{0}N^{*}\exp\left(-\frac{Q_{G}}{RT}\right)\frac{RT^{2}}{\varPhi}\frac{1}{\varPhi}\frac{1}{Q_{G}}\cdot$$

$$\left(q(x_{G}(T)) - \frac{T_{0}^{2}q(x_{G}(T_{0}))}{T^{2}}\exp\left(-\frac{Q_{G}}{R}\left(\frac{1}{T_{0}} - \frac{1}{T}\right)\right)\right) + Vgv_{0}N_{0}\exp\left(-\frac{Q_{N} + Q_{G}}{RT}\right)\left(\frac{RT^{2}}{\varPhi}\right)^{2}\frac{q(x_{G})}{Q_{G}Q_{N}}\cdot$$

$$\left(q(x_{\rm N}(T)) - \frac{T_0^2 q(x_{\rm N}(T_0))}{T^2} \exp\left(-\frac{Q_{\rm N}}{R} \left(\frac{1}{T_0} - \frac{1}{T}\right)\right) \right) - Vgv_0 N_0 \exp\left(-\frac{Q_{\rm N} + Q_{\rm G}}{RT} \left(\frac{RT^2}{\varPhi}\right)^2 \frac{q(x_{\rm G})}{Q_{\rm G}(Q_{\rm N} + Q_{\rm G})} \cdot \left(p_2(x_{\rm N,G}(T)) - \frac{T_0^4 p_2(x_{\rm N,G}(T_0))}{T^4} \exp\left(-\frac{Q_{\rm N} + Q_{\rm G}}{R} \left(\frac{1}{T_0} - \frac{1}{T}\right)\right) \right)$$
(11)

To derive the original model, the terms involving T_0 in Eq. (11) are neglected. Actually, this is not the indispensable process to obtain the analytical solution. In this paper, these terms are reserved. Analogous to the treatment in the appendix A of Ref. [5], the explicit analytical expression for x_e for non-isothermal transformation is given as:

$$x_{\rm e} = K_0^n \exp\left(-\frac{nQ}{RT}\right) \left(\frac{RT^2}{\Phi}\right)^n \tag{12}$$

with the temperature-dependent expressions for n, Q and K_0 gathered in Table 1. In combination with different modes of impingement, the real transformed fraction can be given. Such as the impingement during randomly dispersed nuclei, it can be given as:

$$f = 1 - \exp\left(-K_0^n \exp\left(-\frac{nQ}{RT}\right) \left(\frac{RT^2}{\Phi}\right)^n\right)$$
(13)

Clearly, the current model possesses an analogous form to the original model. The only different between these two models is the expression for C_s and C_c (see Ref. [5] and Table 1). As shown in Eq. (13) and Table 1, the original model results provided that the T_0 terms are neglected, and coarse approximations are used (i.e. q(x)=1 and $p_M(x)=1$) in the current model.

4 Evaluation of extended analytical model

The precision of different types of approximations without considering the effect of T_0 has been evaluated in Ref. [15]. In this section, the most accuracy combination of "temperature integral" and "general temperature integral" approximation (i.e. the combination of CAI et al [14] as $p_M(x)$ and ÓRFÃO as q(x) [12]) will be used to illustrate the effect of T_0 .

The transformed fraction and transformation rate can be numerically calculated exactly, as a function of temperature, on the basis of Eq. (6) by numerical integration of Eq. (5) for V^e . These exact results can then be compared with corresponding results from the analytical approaches. Thereby, the accuracy of different models is tested. Using model parameters given in Table 2, in cases of the mixed nucleation, interface-controlled

growth and impingement due to random nuclei dispersion, the transformed fraction can be predicted at different values of T_0 by the original analytical model (i.e. Ref. [5]) and the current model (i.e., Eq. (13) with Table 1) (see Figs. 1(a)–(c)). Accordingly, the transformation rate can be obtained for different models (see Figs. 1(e)–(f)). Using the same values for the model parameters, the numerical calculations are performed.

As shown in Fig.1, the original analytical model prediction deviates largely from exact values, and it becomes worse and worse with increasing T_0 . However, the current model prediction is always in good agreement with the numerical calculation even if for the transformation with high T_0 . It can also be seen from Fig.1 that the model predications without considering T_0 (i.e. the original analytical model) become better and better as Φ increases for a certain T_0 . It can be explained

that, with increasing Φ , the temperature range for overall transformation increases, accordingly, the strengthen of T_0 effect decreases.

Evolutions of *n* and *Q* with *f* are shown in Fig. 2. For clarity, only the values for *n* and *Q* of the transformation with $T_0=1000$ K and $\Phi=5$ K/min (see Fig. 1(c)) are shown. It can be seen that the kinetic parameters for different models vary considerably. The deviation of transformed fraction and transformation rate for different models from the exact values must be derived from the inaccurate prediction of the kinetic parameters. This implies that the kinetic parameters due to the current analytical model should be more precise.

5 Conclusions

The analytical process incorporating the effect of the initial transformation temperature and the accurate "temperature integral" approximations is presented. The newly derived analytical model possesses an analogous form to the original analytical model. If the T_0 terms are neglected and the coarse approximations for "temperature integral" are used in the newly derived analytical model, it leads to the original analytical model.

Fig. 1 Comparison of transformed fraction and transformation rate between model predictions, at $T_0=900$ K (a, b), 950 K (c, d), and 1000 K(e, f), in cases of mixed nucleation, interface-controlled growth and impingement due to random nuclei dispersion

Fig. 2 Evolution of growth exponent *n* (a) and overall effective activation energy *Q* (b), with transformed fraction calculated by different models at $T_0=1000$ K and $\Phi=5$ K/min

Numerical approach has demonstrated that, once T_0 , as compared with the temperature range considered, is so high that cannot be neglected, the newly derived model prediction for transformed fraction and transformation rate is in better agreement with the exact numerical calculation than the original model prediction. And the kinetic parameters due to the newly derived analytical model are more precise.
