Received 7 March 2012; accepted 16 April 2012

Abstract: Thermodynamic analysis of the possibility of silver nanocrystalline preparation by high energy milling silver oxide was investigated. The molar Gibbs free energy function of mechanically activated samples was calculated from the structural defects such as amorphization, dislocation and surface energy. According to the molar Gibbs free energy function, the equilibrium temperature of mechanical reduction of silver oxide milled for 21 h was estimated at about 304 K. Consequently, at this temperature silver oxide cannot be stable and will transform to silver during the milling.

Key words: silver nanocrystalline; silver oxide; Gibbs free energy function; mechanical activation

1 Introduction

Mechanochemistry is a branch of science dealing with the chemical and physicochemical changes of materials due to the effect of mechanical energy [1]. Recently, mechanochemistry has been widely applied in many fields, such as preparation of intermetallic compounds, composites and complex oxides. nanocrystalline substances and nanomaterials [2-5]. According to the literature, the science base of mechanochemistry suffers from conceptual principles [6-9], especially the thermodynamics. Hence, finding a set of systematic and appropriate theory to explain the thermodynamic of mechanochemical process may be verv useful.

During the mechanical milling over a very short time and space scale, the reactants may emit radiations to form a special plasmatic state and start chemical reaction under the action of great quantity of energy which is set free at the high-speed impacts. Once this step is over, the systematic energy drops rapidly and then structure relaxation occurs, where the rest energy is accumulated in solid in the form of structural disordering and structural mobility [10-12]. During mechanical treatment, non-equilibrium intermediate phase may be created [6,13] and consequently the formation of final product may lag behind the structural changes. Thus, in order to better explain the thermodynamic process of mechanochemical reaction, besides considering the classical chemical reaction thermodynamic, the thermodynamic of structural evolution should be employed as well.

In this study, the fundamental thermodynamic relations are proposed to impose in mechanochemical research areas, aiming to improve the conceptual principles of mechanochemical reaction thermodynamics. Taking for an example, the mechanochemical preparation of silver nanocrystalline by high energy ball milling silver oxide powders, and the thermodynamic analysis of the possibility of transformation are investigated.

2 Experimental

Ag₂O powders (99%, 5–40 μ m) were used as starting materials for mechanical milling in a planetary ball mill. Details of ball milling process are given in Table 1. The phase identification and structural changes of the products were investigated by Philips PW-1730 X-ray diffractometer (XRD) using Cu K_a radiation. The line broadening owing to the instrument was computed from Warren's method [14]. Peak position (2 θ), the

full-width at half maximum (FWHM), and area under peak (A) were obtained from the XRD spectra. The OriginPro 8 software was used to obtain these parameters, among which the Ag₂O planes were selected for the profile analysis.

3 Results and discussion

Figure 1 shows the XRD patterns of milled samples with milling time. The patterns of powders milled up to 20 h show only the presence of Ag_2O phase. During the first 20 h of milling, the peak intensity was decreased due to the decrease of the size of silver oxide crystallites. The traces of silver could be observed after 21 h milling.

Fig. 1 XRD patterns of milled samples as function of milling time

Backscattered electron image of milled powders after 21 h in Fig. 2 qualitatively confirmed the presence of Ag particles by contrast phases between Ag (bright spots) and Ag₂O (gray flakes). Also, the Ag₂O particles were crashed and displayed brittle fracture surfaces that are the characteristics of brittle ionic crystals. While, the Ag particles were generally round and spherical in shape and displayed more homogenous size distribution compared with Ag₂O particles.

Fig. 2 Backscattered electron image of milled powders after 21 h

According to the literature, the energetic condition of mechanically activated materials could be generally explained by the following structural defects [15]: the specific energy of dislocation density, the energy of amorphization, the specific energy of surface area to the surroundings or to a second phase.

The contribution of amorphization energy to the total energy changes is 93%–98.5%. Similar energy distributions are reported for quartz, calcite, magnesite, kaolinite, iron and periclase [16].

3.1 Calculation of specific energy of dislocation density

The classical energy balance observations of Griffith on crack propagation of an elastically isotropic substance show a functional relationship between the critical tensile stress of crack propagation and crack length. Other studies suggested that such ideal behavior does not apply to the majority of crack sensitive materials and must be modified [17]. The modifications of Griffith's ideas for mechanical activation condition can result in a recast relation in terms of fracture mechanics concepts [18].

$$K_{\rm IC} = Y \sigma_{\rm c} a^{1/2} \tag{1}$$

where K_{IC} is the critical stress intensity factor for crack propagation; *Y* is a geometrical factor related to the shape of the crack; σ_c is the critical tensile stress for crack propagation; *a* is the crack length. According to Eq. (1), by decreasing the crack length, the tensile stress of crack propagation increases. Hence, primary fracture and size reduction of silver oxide occur by propagation of the largest cracks at relative low σ_c . With increasing the stored energy by milling, the particle and its crack length decrease to micron or submicron in which σ_c becomes very large. Consequently, rather than fracture, generation of dislocations is the predominant phenomenon in mechanical activation [18].

The change in molar Gibbs free energy of milled silver oxide due to dislocations, ΔG_d , is a function of molar enthalpy of dislocations, ΔH_d , and molar entropy of dislocations, ΔS_d , as Eq. (2) [18]

$$\Delta G_{\rm d} = \Delta H_{\rm d} - T \Delta S_{\rm d} \tag{2}$$

According to Cottrell hypothesis, dislocations are essentially one-dimensional defects, and estimation was proposed that their entropy effect is significantly small. Therefore, $T\Delta S_d$ becomes negligible with respect to ΔH_d [19]. Hence, ΔG_d is almost equal to Eq. (3):

$$\Delta G_{\rm d} \approx \Delta H_{\rm d} = \rho M_{\rm V} [b^2 \mu_{\rm s} / (4\pi)] \ln[2 / (b\rho_{\rm d}^{0.5})]$$
(3)

where *b* is the Burgers vector of the dislocation; μ_s is the elastic shear modulus; M_V is the molar volume; ρ is the dislocation density [18]. The direction of Burger's vector of silver oxide is similar to cuprite [18,20]. Thus, the value of Burger's vector for silver oxide in direction (100) is found to be 4.81×10^{-10} m [20]. M_V = 3.245×10^{-5} m³/mol is the molecular mass of silver oxide, 231.735×10^{-3} kg/mol, divided by its density, 7140 kg/m³, [15,21]. In order to determine the μ_s , the value of elastic modulus of silver oxide, *E*, must be calculated using

$$E=3K(1-2v) \tag{4}$$

where *K* is the bulk modulus of Ag₂O (74 GPa), and *v* is Poisson ratio and is about 0.3 [18,22]. From Eq. (4) elastic modulus of Ag₂O is estimated to be 88.8 GPa. Consequently, the μ_s of Ag₂O is calculated to be 34.2 GPa using

$$\mu_{\rm s} = E/2(1+\nu) \tag{5}$$

The dislocation density ρ was calculated from the relationship $\rho = \langle \rho_D \rho_{\varepsilon} \rangle^{0.5}$, where $\rho_D = (3/D^2)$ (dislocation due to domain size), $\rho_{\varepsilon} = k(\varepsilon^2)/b^2$ (dislocation due to lattice strain); *D* is the crystallite size; *k* is a material constant of about 2; ε is the lattice strain; *b* is the Burger's vector. The average crystallite size and internal strain were calculated using Williamson–Hall plot [23].

Figure 3 shows the changes in crystallite size and lattice strain with milling time. Clearly, one can decompose the time dependence of the microstructure in two domains.

For time up to 20 h, the crystallite size of Ag_2O decreases rapidly to a value near 23 nm as a result of mechanical shocks induced by the milling process. At the same time, the strain increases to 0.75%. During the first 20 h, the energy provided by the milling was consumed

to generate the crystal imperfections such as dislocations and grain boundaries.

Fig. 3 Evolutions of size and strain with milling time

Between 21 h and 50 h, after preparation of Ag crystallites, the rate of size decreasing and the rate of strain increasing of Ag_2O crystallites are decreased as a result of thermal annealing. In other words, as expected the strain should increase with milling time because the material is put under increasing stress. Simultaneously, the temperature within the vial rises and the thermal energy anneals the sample, namely, the strain reduces. If one of these two parameters dominates, the time dependence of strain and size would be more drastic than the observed one. So it seems that under the specific conditions of our synthesis, increasing temperature relatively decreases the rates of changes of size and strain with milling time.

3.2 Calculation of amorphization energy

The degree of crystallinity (DOC) is defined as

$$DOC = (A_t / A_0) \tag{6}$$

where A_0 and A_t are the areas under the (111) plane diffraction peak of non-activated and activated samples in time *t*, respectively [24,25]. Thus, the amorphization energy of milled Ag₂O could be calculated from

$$\Delta G_{\rm am} = \left[1 - (A_t / A_0)\right] \Delta \overline{G}_{\rm am} \tag{7}$$

where $\Delta \overline{G}_{am}$ is the molar amorphization energy of Ag₂O and can be estimated as follows [18]:

$$\Delta \overline{G}_{\rm am} = \Delta \overline{H}_{\rm m} (1 - T/T_{\rm m}) \tag{8}$$

where $\Delta \overline{H}_{m}$ is the molar enthalpy of melting Ag₂O at T_{m} . Although the value of $\Delta \overline{H}_{m}$ is unknown due to the decomposition of Ag₂O at about 553 K, since the crystal structure of Cu₂O is similar to Ag₂O, the enthalpy change in melting Ag₂O can be assumed to be the same as that of Cu₂O (56.9 kJ/mol) [26], consequently:

Gholam Reza KHAYATI, et al/Trans. Nonferrous Met. Soc. China 23(2013) 543-547

 $\Delta \overline{G}_{\rm am} = 56900 - 102.89T \tag{9}$

3.3 Calculation of specific energy of surface area to surroundings or to a second phase

The surface energy of particles in thermodynamics is estimated from [1]

$$\Delta G_{\rm surf} = \sigma \Delta A \tag{10}$$

where σ is the specific surface and ΔA is the change of overall surface energy of a solid. It was estimated for mechanical activation of ionic crystals that the surface energy, ΔG_{surf} , corresponds approximately to 10% of overall Gibbs energy of mechanically activated samples [1], thus

$$\Delta G_{\text{surf}} = 0.1(\Delta G_{\text{am}} + \Delta G_{\text{d}}) \tag{11}$$

3.4 Calculation of molar Gibbs free energy of mechanically activated Ag₂O

The following reaction has been considered to estimate the molar Gibbs free energy of milled silver oxide:

$$Ag_2O(s)=2Ag(s)+(1/2)O_2(g)$$
 (12)

where the standard Gibbs free energy of reaction (12) is [7]

$$\Delta G^{\Theta} = G_2^{\Theta} - G_1^{\Theta} = 30540 - 66.11T \tag{13}$$

Consequently, at the atmosphere pressure, $p(O_2)=21.27825$ kPa, the Gibbs free energy change of non- activated Ag₂O was estimated from

$$\Delta G_{\text{nac}} = \Delta G^{\Theta} + RT \ln[p(O_2)]^{1/2} = 30540 - 72.60T \quad (14)$$

The molar Gibbs free energy change of mechanically activated Ag₂O after time *t*, i.e. ΔG_T , can be calculated from Eq. (15) [1]

$$\Delta G_T = \Delta G_{\rm nac} - \Delta G_{\rm ac} \tag{15}$$

where ΔG_{ac} is estimated from

$$\Delta G_{\rm ac} = \Delta G_{\rm am} + \Delta G_{\rm surf} + \Delta G_{\rm d} \tag{16}$$

Consequently, ΔG_T is computed from.

$$\Delta G_T = 30540 - 72.60T - 1.1\{\rho M_v [b^2 \mu_s / (4\pi)] \cdot \\ \ln[2/(b\rho_d^{0.5})] + [1 - (A_t / A_0)](56900 - 102.89T)\}$$
(17)

The values of ρ and A_{21}/A_0 of the sample milled for 21 h are measured to be 7.31×10^{14} m² and 0.91, respectively. Figure 4 shows the ΔG values of non-activated and mechanically activated samples milled for 21 h with temperature according to Eqs. (15) and (17). As shown, the equilibrium temperature of the 21 h-milled sample was 304 K. Accordingly, between 304 to 461 K, the Gibbs free energy change of reaction (12) in mechanically activated condition was negative while the Gibbs free energy change of unmilled sample was positive. Thus, by extending the milling time the Ag_2O phase is not stable and the reaction proceeds toward the formation of Ag. This result was also confirmed by the vial temperature after 21 h milling that was measured by thermometer at about 305 K.

Fig. 4 Total Gibbs free energy of mechanochemical reaction before and after 21 h milling

4 Conclusions

The thermodynamic principles of mechanochemical reaction investigated using fundamental were thermodynamic relations. Mechanochemical reduction of Ag₂O was studied as a case. According to the calculated total Gibbs free energy function of mechanochemical reaction after 21 h milling, the transformation temperature is about 304 K. The negative value of ΔG near 304 K shows that the formation of silver has started a few moment before the 21 h milling and the reduction reaction proceeds toward the production of silver. The results showed that the amorphization energy was the most affecting parameter on Gibbs free energy function of mechanically activated Ag₂O.
