Received 19 September 2005; accepted 14 October 2005

Abstract: A stable \(\delta\)- and \(\beta\)-bismuth trioxide was prepared at room temperature by vacuum vapor-phase oxidation. The average crystal size of products was 14.6 nm (by XRD), the \(d(0.5)\) value was in the range from 62 nm to 69 nm, and geometric standard deviation(GSD) was from 1.42 to 1.64. The results show that \(\delta\)-Bi\(_2\)O\(_3\) is formed when quenching rates is rapid and \(\beta\)-Bi\(_2\)O\(_3\) is formed when it is slow. The size of grains increases with rising reaction temperature, flow rate of carrier gas, residual pressure of system and longer growing time of grains.

Key words: \(\delta\)- bismuth trioxide; \(\beta\)-bismuth trioxide; vacuum vapor-phase oxidation; nanometer particles

1 Introduction

Bismuth trioxide is an important function material. It exits in four polymorphs\([1-4]\), i.e. the monoclinic \(\alpha\)-phase, the tetragonal \(\beta\)-phase, the body-centered cubic(bcc) \(\gamma\)-phase and the face-centered cubic(fcc) \(\delta\)-phase. Below 730 °C, bismuth trioxide exits as the monoclinic \(\alpha\)-phase, and above this temperature, it exits as the fcc \(\delta\)-phase\([5]\). Because phase transformation lags behind temperature changing, when cooled from temperatures above 730 °C, fcc \(\delta\)-phase of bismuth trioxide will undergo a transformation into one of the two metastable phases, the tetragonal \(\beta\)-phase or bcc \(\gamma\)-phase, before reverting to the monoclinic form\([6]\).

\(\delta\)-Bi\(_2\)O\(_3\) has a fluorite-type structure with one quarter of the oxygen ions missing in an ordered oxygen lattice. The oxygen lattice sites are occupied randomly by oxide ions which can move from site to site through the bismuth sub-lattice. So \(\delta\)-Bi\(_2\)O\(_3\) has high ionic conductivity\([7]\). At the same time, its conductivity is about 2 orders of magnitude higher than zirconia-system electrolytes widely used at present. Therefore, it is an extremely promising solid electrolyte material and can be used as solid oxide fuel cells and oxygen sensors. However, a significant limitation is that it exists stably only between 730 °C and 825 °C\([8]\).

With the development of the studies for nanometer materials, scientists found that nanometer size of crystal can stabilize metastable materials such as ZrO\(_2\)\([9, 10]\). This rule was applied in the preparation of pure \(\delta\)-Bi\(_2\)O\(_3\) and \(\beta\)-Bi\(_2\)O\(_3\). BOHANNAN et al\([11]\) prepared nanocrystalline films of \(\delta\)-Bi\(_2\)O\(_3\) by electrodepositing at 65 °C directly from alkaline solutions of tartrate-complexed Bi(III). The author proposed that the high temperature form of the oxide was stable due to the nanocrystalline (70 nm) size of the particles in the film. MONNERAU et al\([12]\) prepared stable \(\beta\)-Bi\(_2\)O\(_3\) at room temperature with the decomposition of different bismuth(III) oxalate precursors by controlled transformation rate thermal analysis, which were obtained from the reaction of Bi(NO\(_3\))\(_5\)H\(_2\)O and H\(_2\)C\(_2\)O\(_4\)•2H\(_2\)O.

Some processes of aforementioned preparing methods are operated in the solution, in which some components may be adsorbed at the interface of nanometer bismuth trioxide. In general, it is more difficult that the components are completely eliminated.
by washing, and the remains may influence the conductivity of bismuth trioxide. Additionally, the chemical processing methods have disadvantages of environmental protection. In this paper, an alternative, environmentally benign preparing method was presented—vacuum vapor-phase oxidation that was used for preparing bismuth trioxide. And how to control the size and the polymorph of particles were also discussed.

2 Experimental

2.1 Apparatus

Fig.1 shows the apparatus for preparation of bismuth trioxide which was made by ourselves. The middle section of a porcelain pipe (length 1 000 mm, inner diameter 36 mm) was heated to the desired temperature by an electric-tubular furnace to evaporate bismuth from a porcelain boat. The furnace temperature was controlled by a temperature controller connected with a thermocouple. Air or oxygen (industrial pure gas from Changsha supply-gas Ltd) was introduced through the pipe inlet (feed side) to the system using a 6 mm copper tube in length. The outlets of the porcelain pipe on the other side were connected with the collecting system and vacuum pump. Two model mechanical vacuum pumps were used under different experimental conditions, model ZXQ-2 and 2XZ-1, respectively. All tube connections were spread with vacuum flanges to allow gas-tight operation at subatmospheric pressure.

![Fig.1 Schematic of apparatus for preparation of bismuth trioxide](image)

2.2 Experiment

The apparatus was connected as described in Fig.1, firstly. After the set temperature was reached, the rubber plug was taken down, and the porcelain boat loaded with about 5 g bismuth granules which was crushed from bulk bismuth (industrial grade, from Zhuzhou Metallurgy Co) and 0.3 g adding agent (preventing bismuth melt from oxidation) was placed at the appropriate position in the porcelain pipe. Next, closed tightly the feed side of the pipe with the rubber plug, switched on the vacuum pump and adjusted carrier flow rates to the operating conditions with needle valves. Experiments were carried out from 1 005 °C to 1 140 °C, at carrier flow rates of 40—200 L/h, the two different model mechanical vacuum pumps were used for changing drag force. The apparatus should be slowly cooled down to room temperature after all experiments were performed.

2.3 Characterization

Morphology of bismuth trioxide was analyzed by a Sirion200 (FEI Co) scanning electron microscope (5 kV accelerating voltage). The powder was stuck on the surface of an electric double-faced stickiness film and blown off the redundant powder on the surface. In addition, the samples were sputter coated with about 100 Å Pd to improve its conductivity.

The structure of the sample was characterized by Japan Rigaku D/Max-2500 X-ray diffractometer (CuKα radiation, 1.540 65 Å, 40 kV, 300 mA). X-ray diffraction analysis was performed over an angle of 10°≤θ≤90° in steps of 0.02°. The average crystal size of the powder was calculated according to Scherrer’s equation

\[ D = \frac{0.89}{\beta \cos \theta} \]

where \( \lambda \) is the X-ray wavelength, \( \beta \) is the line with at half maximum height and \( \theta \) is the diffraction angle. The (400) diffraction peak was selected for calculation of the average crystal size so that the size of bismuth trioxide with different polymorphs was comparable.

The granularity distribution of powders was determined by Laser Particle Sizers (Mastersizer 2000, Malvern Instrument Ltd). The powder was suspended in water before measurement. The detecting size range was 0.02 μm to 2 000 μm. The \( d(0.5) \) value was the measurement results analyzed with Mastersizer 2000 software(version 5.0). GSD was calculated with commercially available Matlab 6.0 software using the following equation[13]:

\[ \ln \sigma_g = \left( \frac{\sum n_i (\ln d_i - \ln d_g)^2}{N-1} \right)^{1/2} \]

where \( n_i \) is the number of particles with diameter of \( d_i \), \( d_g \) is the geometric mean diameter, and \( N \) is the total number of particles.

3 Results and discussion

The preparing processes of bismuth oxide by vacuum vapor-phase oxidation include evaporation of bismuth, formation of gaseous molecules of bismuth oxide by chemical reaction of bismuth and oxygen, nucleation, condensation and coagulation. The average
size and granularity distribution of particles strongly depend on the process conditions mentioned above. Different size and different polymorphs of bismuth oxide were prepared by controlling the experimental conditions, shown in Table 1.

### 3.1 Polymorph of bismuth trioxide

Table 1 shows that when carrier gas is air, the products prepared at different evaporation temperatures (No.1, 2, 3 in Table 1) or different carrier flow rates (No.4, 5, 6, 7 in Table 1) exhibit the same XRD patterns (Fig.2), which correspond exactly with the PDF#27-0050, indicating that bismuth trioxide powders are tetragonal $\beta$-Bi$_2$O$_3$. And when the vacuum pump with larger dragging rates is used (No.9 in Table 1), all diffraction peaks are assigned to the face-centered cubic phase bismuth trioxide (Fig.3) as reported in PDF#16-0654, indicating that the bismuth trioxide powders are fcc $\delta$-Bi$_2$O$_3$.

In the processes, the bismuth vapors reacted with oxygen in the carrier gas to form the bismuth oxide. When the temperature of bismuth oxide decreased because of heat exchange, it began to solidify and subsequently, the transition of cubic $\delta$-phase to monoclinic $\alpha$-phase occurred. The decreasing temperature rates of bismuth oxide were very rapid because of large temperature gradient between evaporation region and collecting region and very small size of particles. Consequently, phase transition could not keep with the temperature change in the particles so that metastable $\delta$-Bi$_2$O$_3$ and $\beta$-Bi$_2$O$_3$ were formed. According to the Laplace equation, the additive pressure of the liquid droplets with the nanometer grade could reach MPa grade. After such liquid droplets solidified, a higher inner pressure could exist in the particle, which was in favor of the stability of metastable phases[14]. And when the dragging rates of large vacuum pump were rising, the quenching rates were quickened correspondingly. Then $\delta$-Bi$_2$O$_3$ was formed. And $\beta$-Bi$_2$O$_3$ was formed at lower quenching rates. Both polymorphs of bismuth trioxide were stable at room temperature because their sizes were nanometer.

3.2 Size of bismuth trioxide

3.2.1 Influence of process conditions on size of bismuth trioxide

In our experimental temperature range (from 1005 °C to 1140 °C), the saturated vapor pressure of bismuth oxide obtained from the gaseous reaction was very low. Such systems were known as constant rate aerosol reactors[15], in which the initial homogeneous nucleation finished in a limited duration. Subsequently, the nucleation and growth of the particles will simultaneously occur, which leads to the content decreasing of the gaseous bismuth oxide. The systems reached the balance if the rate of bismuth oxide formed from the gaseous reaction was equal to its rate lost from the nucleation and growth. According to the nucleation theory, the number of nuclei was constant at balance state[16]. Therefore, the size of final products was determined by the initial nucleating number, the growing rate and duration of the particles at balance state. The growing duration of the particles was inversely proportional to the quenching rate.

The rise of temperature enhances formation of the bismuth oxide, leads to high supersaturation degree and increases the number of the initial nucleation, which consequently decreases the particle size. However, after the constant state of the system is reached, the rise of the temperature promotes the growth of grains and leads to the greater size of particles. In our experiments, the size of the grain becomes greater as temperature rises (Fig.4).

The increase of the carrier gas flow rate increases the residual pressure of the system, which enhances the eddy flow of gas in the system because the gas stream is obstructed by the porcelain boat in the reaction pipe, increase residence time of the particle, prolongs growing duration of the particle and leads to larger particles. Therefore the size of grains increases with the carrier flow rate or the residual pressure of the system (Fig.5).

The size of grains decreases with the increase of the drag force (No.8 and No.9 in Table 1) which can raise the carrier flow velocity and quenching rate, reduce the growing duration of grains.

3.2.2 Size distribution of particles

To estimate the size distribution of the particles, the products were measured by the Laser Particle Sizers listed in Table 1. The size of particles was estimated to be from 62 nm to 69 nm, geometric standard deviation (GSD) is from 1.42 to 1.64. These results show that the size of particles is small and size distribution is narrow.

3.3 Morphologies of bismuth trioxide

Fig.6 shows the SEM images of representative products. It can be seen that all the particles are near spherical shape, and do not change their shape with process conditions. But process conditions affect the size of grains substantially. The maximum size of grains is respectively 113.4 nm at 1140 °C under 6.29 kPa of residual pressure (No.3 in Fig.6), 69.19 nm at 1059 °C and 6.35 kPa of residual pressure (No.2 in Fig.6), 40.36 nm at 1059 °C under 3.38 kPa of residual pressure (No.8 in Fig.6) and 28.82 nm at 1059 °C under 2.32 kPa of residual pressure (No.9 in Fig.6). This changing tendency is consistent with the results obtained by XRD.

4 Conclusions

1) The apparatus of bismuth oxide prepared by vacuum vapor oxidation in this paper creates a quenching circumstance in which phase transition of
bismuth oxide lagged behind the temperature changing so as to produce nonequilibrium $\delta$-Bi$_2$O$_3$ and $\beta$-Bi$_2$O$_3$. The larger inner pressure exists in the nanoparticles stabilized $\delta$-Bi$_2$O$_3$ and $\beta$-Bi$_2$O$_3$ at room temperature.

2) The average size of the minimal grain prepared in our experiments is 14.6 nm (measured by XRD). The $d(0.5)$ value of the products determined by the Laser Particle Sizers is from 62 nm to 69 nm, and by GSD is from 1.42 to 1.64. These results show that the size of particles is small and the size distribution is narrow.

3) The size of the product is influenced by some factors such as temperature, flow rate of carrier gas as well as residence time. The size of grains prepared by vacuum vapor-phase oxidation increases with the increasing reaction temperature, growing time of grains, flow rate of carrier gas and residual pressure of system.
